OBITUARY

MISCELLANY

GUIDE TO AUTHORS

● Review articles should be aimed at a relatively wide readership. Many reviews are invited, but submitted articles may also be accepted; it is advisable to consult us before writing a review article.
● Articles may be up to 3,000 words long with at most six displayed items (figures and tables); they are reports of major research developments.
● Letters are brief reports of original research of unusual and wide interest, not in general longer than 1,000 words; they have at most three or four displayed items.
● 'Matters Arising' permits short discussion (up to 300 words) of papers that have recently appeared in *Nature*.
Articles should be accompanied by an abstract of not more than fifty words. Letters should begin with a paragraph giving the background and main conclusion in terms intelligible to as wide a readership as possible.
 Manuscripts may be submitted either to London or New York. Three typed copies should be submitted, each including lettered copies of figures. Typing (including references) should be double spaced. The title should be brief and informative. Pages should be numbered. References, tables and figure legends should start on separate pages. Experimental detail vital to the paper yet which would interrupt the narrative is best placed in the figure legends. Units should be identified in the margin on their first appearance. Equations should occupy single lines if possible: exp(*a*) is preferred to e^*a* if '*a*' is more than one character.

References are indicated by superscripts in the text. See any contemporary *Nature* for style, but note:
(i) only one reference number need be used if the reference is to several papers by identical authors.
(ii) first and last pages of references should be cited.
 Abbreviations should follow the *World List of Scientific Periodicals*, fourth edn (Butterworth, 1963-65). Symposia are often difficult to refer to and only published or soon-to-be-published volumes should be mentioned in references. Their publisher and place of publication should be clearly indicated 'Personal communication' and 'unpublished' should be incorporated in text.
 Artwork should be sent with the manuscript and clearly marked with author's name and the figure number. Line drawings should be either photographic prints or in Indian ink on heavy cartridge paper, tracing paper or similar materials. Most figures are reduced to one column width so originals should be about as wide as a page of *Nature*. To enable figures, particularly maps, to be edited in the same style as the text, they should contain only essential material. Ideally, an unlettered original and three lettered copies should be provided; labelling on halftones should, if possible, be avoided entirely. Magnifications quoted should be for the figures as submitted. We are always glad to see artwork for possible use on the cover, but cannot guarantee its return.
 In order to save on postal expenses we return only the top copy and artwork of manuscripts that we cannot publish.
 Nature's publishing policy is outlined in **258**, 1 (1975) and **264**, v, 11 Nov. (1976).

This issue of *Nature* contains fewer Articles and Letters than usual because of an industrial dispute which has affected the typesetting of manuscripts accepted for publication.

GUIDE TO AUTHORS

Getting down to the finer details of microelectronics

As a leading manufacturer, and user, of micro-electronic technology, Philips is constantly searching for techniques that will improve the production process, or the product, or – ideally – both. This objective has now been achieved with the development of the 'Beamwriter' vector scan lithography system. In fact, it's the only production-oriented vector scan electron beam writing system available in the world.

Compared to conventional optical lithography techniques, vector scanning produces significant savings in the time taken to produce a set of masks or reticles; hours instead of days. It is also much more efficient than the raster scan E-beam method because the writing beam is directed only to points where exposure is required. The Beamwriter also generates an exposure dosage twenty times greater than other

When in London do as the Romans did—
settle on the Barbican.
(It's the perfect place for a conference.)

It's a long time since the Romans left. (About 1,500 years, in fact.) But you can still see traces of their occupation – including remains of the original Roman city wall.

The Barbican Centre is located in the heart of the City of London. So it's surrounded by centuries of history and culture plus the bustle and excitement of one of the world's leading financial communities.

The Barbican Centre itself, however, will be among the most modern and well equipped conference centres available.

There's a spacious conference hall. A variety of lecture theatres, seminar and committee rooms. A Film Theatre – with the most advanced audio-visual equipment. The Barbican Theatre. Interpretation facilities for six languages. A display and exhibition area. Plus a plentiful supply of bars and restaurants.

The Barbican caters for cultural appetites, too. The Royal Shakespeare Company will have its permanent home there. So will the London Symphony Orchestra. And the Guildhall School of Music and Drama. There's an Art Gallery. A Sculpture Court.

In other words, it's as civilised a forum for a conference as even the Romans could have dreamed of.

We're already taking bookings from 1981 onwards.

So, if there's anything more you'd like to know about the Barbican, just contact our Conference Sales Director.

And don't worry. She speaks English. Not Latin.

Barbican Centre
11 Cromwell Tower, Barbican, London EC2Y 8DD, England. Telephone: 01-638 4141.
A display and exhibition area totalling 8,000 square metres gross (86,000 square feet).

The Barbican Hall comfortably seats 2,000 delegates.

A variety of lecture theatres, seminar and committee rooms to take anything from 5 to 265 people.

The Film Theatre seats 275 people.

The Barbican Theatre seats 1,150.

THE ECOLOGY & CONSERVATION OF LARGE AFRICAN MAMMALS

S. K. ELTRINGHAM

DEPARTMENT OF APPLIED BIOLOGY, UNIVERSITY OF CAMBRIDGE.

£15.00; 288pp; ISBN 0 333 23580 0.

"Keith Eltringham has produced a valuable book which treats the ecology of large African mammals in the widest context. In a compact volume he considers their social behaviour, population, biology, and feeding in an ecological framework. Perhaps the most important sections are the last three chapters which deal with conservation, wild life management, and man and national parks".
BIOLOGIST, APRIL 1980.

"Eltringham's book is written as a textbook for undergraduates but he also had in mind the value of making the book of interest to those with a more cusory contact with African habitats. Accordingly, it is written with a pleasant directness, lack of jargon, and wry humour".
TIMES HIGHER EDUCATION SUPPLEMENT, MARCH 1980.

"The appearance of this book is timely. Many talk about conservation without doing anything about it. Keith Eltringham has done an excellent job by providing much needed information. He has obviously drawn from his vast experience as a wildlife biologist in East Africa for many years. Writing about a subject he knows so well makes the account vivid and very much alive".
AFRICAN JOURNAL OF ECOLOGY, MARCH 1980.

"This immensely readable book will be essential for any undergraduate studying mammals and ecology but it will also be attractive to a wider audience – not only those who have been fortunate enough to visit Africa. Many people are now familiar with these animals through films, television, zoos and safari parks, and this book will interest all those who wish to know how they are living together and surviving in the world.
BRITISH BOOK NEWS, APRIL 1980.

Macmillan books are available from all leading booksellers.

In case of difficulty write to Frances Roach, Macmillan Retail Ltd., Houndmills, Basingstoke, Hampshire, England, enclosing remittance plus 70 pence (p&p).

1 May 1980

Does science need a tax-break?

SHOULD President Carter introduce generous new tax incentives — in particular increased deductions for money spent on research and development — to help reverse the productivity decline widely claimed as a major source of the nation's economic problems? American business is convinced that he should: the Committee for Economic Development, for example, synthesising the views of many large corporations, said earlier this year that 'top priority' should be given to appropriate tax changes as a means of stimulating technological innovation.

The administration itself is less certain. While accepting the argument that tax relief for R and D could help increase the rate of innovation (and even this is yet to be supported by hard data) administration officials also point to the cost of such measures in terms of reduced federal revenues. Revisions to the tax law have long been promised, and many expected them to be included in the package of measures to spur innovation which the President presented to Congress last autumn. But such moves have since been overshadowed by attempts to balance the budget.

At present, although private companies can deduct R and D expenditures as running expenses, no special incentives exist for investment in R and D equipment. This is in contrast to France, for example, where accelerated depreciation is allowed on all investments in research. Or Germany, where a 7.5 per cent tax-free cash subsidy is granted on money spent on R and D facilities.

Current demands to reduce the tax burden represent the intersection of two trends. The first is a general political thrust to reduce taxes on both individuals and corporations, represented most vividly by a proposal before Congress for an immediate 30 per cent cut in personal income tax. The other is a more detailed argument that, in order to encourage more private R and D, it should be made more attractive than other possible investments — with the tax system being used to this end.

In general the two trends reinforce each other. But there are ways in which they could conflict. For example, political enthusiasm for tax relief to major corporations has produced broad-based support for a bill introduced by representatives James R Jones and Barber B Conable which would shorten the time over which companies could write off capital investments. Rather than using a 'useful life' formula which differs from industry to industry, the bill proposes fixed depreciation times of ten years for buildings, five for machinery and equipment, and three for light vehicles (hence referred to as the 10-5-3 proposal).

Supporters of the bill, which has more than 300 co-sponsors in the House of Representatives and would include R and D equipment, argue that it would free capital for more lucrative investment, and is thus precisely the type of measure needed to raise the general level of economic activity. Critics, however, have suggested that the benefits of such a bill would be skewed in favour of capital-intensive industries, and not necessarily high technology firms with large R and D costs, where the 'write-off' time may already be short. It is also argued that the Jones-Conable bill would cost $5 billion in the first year, and $25 billion after five years — and that the resultant inflationary pressures could outweight any benefits.

In the light of such objections, a separate proposal has been made by representative Charles Vanik of Ohio. He has proposed a Basic Research Revitalisation Act which would offer tax incentives to companies supporting university research. In particular, companies would be given a 25 per cent tax credit on money deposited in a special research reserve (up to five per cent of the company's business income). And any money taken from this reserve to fund basic or 'exploratory' research in universities could be claimed as a tax deduction, providing it was spent within four years.

Research universities are understandably enthusiastic about the Vanik bill, which has been co-sponsored by over half the members of the House Committee of Science and Technology. As funds for federal support for basic research grow tighter, universities are increasingly looking to industry as a source of financing. A typical example is the announcement expected this week from the Massachusetts Institute of Technology that it is to receive a large grant from the Exxon Company to support fundamental combustion research. Exxon officials have already spoken in support of tax relief for such moves, claiming it would encourage other companies to follow their example.

But the question hanging over the Vanik proposals is whether they would make any significant impact on the problem they are intended to address, namely the nation's declining productivity and the consequent slowdown in economic growth. Most analysts agree that it is not support for R and D itself which is missing, but adequate mechanisms for translating knowledge into useful and acceptable products. A report published last week by the National Science Foundation, for example, shows industrial R and D to be in a surprisingly healthy state, experiencing a five per cent real growth between 1976 and 1977, with a 22 per cent increase in the number of qualified scientists and engineers employed between 1972 and 1977.

Demands for tax incentives to stimulate research, particularly made at a time when the overall level of R and D effort would appear adequate, reflect a desire to short the control of research funds from the public to the private sector. Such a move has obvious attractions to those who would benefit most directly; but whether it is the best solution is a political, not a technical, judgement. The success of Japanese industry in fields from motorcycles to digital watches has been achieved in active partnership with government. In Britain the Spinks report on biotechnology endorses a similar marriage. In the US, the key to rekindling innovation should be better government — not less. □

United States

An excess of doctors...

David Dickson reports from Washington on the levels of manpower in medicine, and womanpower in science.

AFTER fifteen years' rapid expansion, US medical schools are beginning to produce more doctors than the country needs. Earlier this month the Department of Health, Education and Welfare (DHEW) predicted that the surplus could be between 4,000 and 40,000 by 1990; and other estimates make it considerably higher.

Numbers alone, however, hide the fact that not all medical graduates go where they are required. In particular, the more lucrative fields of surgery continue to exert higher attraction than primary health care, especially on those who may leave medical school with outstanding loans of $40,000 to $50,000.

Ironically the current situation is largely the result of the success of the government's previous efforts to fit medical education to social needs. These were initiated in the late 1960s, when a national shortage of doctors led the government to offer generous grants to medical schools willing to increase their enrollments.

With the encouragement of 'capitation' grants (based on the number of students) and funds for the creation of new medical schools, the number of places for medical students has doubled, from about 8,000 to 16,000. And although the rate of expansion has slackened off, there is no indication that it is likely to fall, particularly given the continued excess of applicants over available places.

The consequence of a growing domestic supply plus the influx of foreign doctors during the period of shortage is that, according to figures prepared by DHEW's Bureau of Health Manpower, there will be 600,000 doctors in the US by 1990 — but the need will only be for between 553,000 and 596,000.

Congress' Office of Technology Assessment (OTA) predicts an even wider gap. In a report on the bureau's statistical methodology published last week, it agrees with the supply figure but points out that the projected need is based on a linear extrapolation of an observed increase in the per capita demand for physicians over the period 1968 to 1976.

The OTA report also points out, however, that since 1971 the per capita demand has been falling. And that if this trend is combined with expected demographic changes, the need for doctors by 1990 could be as low as 415,000.

No-one is particularly worried about the surplus itself. Despite the growing signs of a shift away from surgery into general practice, there are still likely to reamin — as

both the DHEW and the OTA report emphasise — fields in need of more doctors, for example, for work among imigrant and minority populations.

The dilemma is over the appropriate response of both the federal government and the medical schools. The Carter Administration is using the over-supply figures to support its proposal that all direct federal aid to medical schools should now be dropped, confining assistance to student grants and loans.

The schools, in contrast, feel that relying on tuition fees alone would place unacceptable pressures on students. And that some form of additional support, not tied to providing health services or to funding research which are both tightly regulated, would now be welcome.

So far the administration's attempt to eliminate capitation grants has met limited success. Although omitted from DHEW's budget request for 1980 last year, they were put back by Congress reacting to pressure from the medical schools. In January the President asked that the capitation grants be withdrawn from the 1980 budget, but again Congress disagreed. A further attempt to cut the money out was made in the President's revised budget request last month among the revisions for 1980. And the issue remains unresolved.

However congressional attitudes are changing, reflecting the schools' acceptance of the current illogic of measures to increase doctor supply. Last week a House subcommittee proposed that, in renewing the health education support legislation which runs out this year, capitation grants should be 'phased-down' by steps of 25% over the next three years. And although remaining agnostic over whether the nation faces an oversupply of doctors, the subcommittee agreed that no new medical schools should receive federal funding.

The main problem facing the schools is the implication of the growth in tuition fees, which can now go as high as $8,000 a year. One approach has been to seek new forms of outside assistance; thirteen private medical schools announced last week that they are to divide $1.3 million next year awarded by the Henry J. Kaiser Foundation to assist students with more forthcoming later to those able to raise matching grant from alumni or elsewhere.

Others are seeking new forms of federal support for teaching. "One way would be to develop a two-part system. All schools would get a certain base amount, and you could then pick and choose programmes which might qualify for additional funding" says Dr Richard Ross, Dean of the Medical Faculty and Johns Hopkins Medical School.

Without some such support, fears are growing that many of the trends which federal funding has encouraged — such as the growing recruitment of students from minority or low-income groups — could be reversed. And that current mismatches between the supply of physicians and health needs may only be exacerbated. □

...and a dearth of women

A political struggle appears to be looming on the Washington horizon over the steps that the US government should take to encourage the participation of women in science.

In passing the National Science Foundation's budget for 1981 last Thursday, the Senate Subcommittee on Health and Scientific Research included a provision for $23 million to be allocated to a new 'women in science' programme within the foundation.

The elements of the programme are broadly similar to those included in a bill introduced last year by Senator Edward Kennedy. They include a new centre for women in science, a special committee within the foundation to examine the position of women scientists, the creation of appropriate university positions, and the appointment of a special assistant to the NSF director.

Subcommittee members say the need for such a programme is shown by the fact that the number of women in science remains

disproportionately low. But to make room for the programme while remaining under the revised ceiling for the NSF's budget proposed by President Carter earlier this month, the committee is recommending a *pro rata* 9% cut on all items listed in the original January budget request.

Although the impact on basic research programmes would be mitigated by the transfer of money that would have been spent on upgrading research facilities, this would cut back their increase from 11% to 7%. Funds for mathematical and physical sciences, for example, would fall from a proposed $260 million to $244 million.

The corresponding House Sub-committee, in voting on the NSF budget last week, kept closer to the administration's revised request for $1,074 million. However, it added applied research and science education items, and cut back the proposed government /industry ocean margin drilling project from $5 million to a $500,000 study by the National Academy of Sciences. □
ELMO Bumpy Torus: dark horse of fusion

To most nuclear engineers, magnetic confinement fusion technology tends to be identified with the familiar doughnut shape of the Russian-designed Tokamak, which gained acceptance over US designs in the early 1960s, and of which 40 are now in experimental operation world wide.

But both Tokamak technology and the less familiar mirror confinement techniques still face many unanswered questions. And two years ago an *ad hoc* review committee appointed by the US Department of Energy recommended that, in the light of such uncertainties, increased support be given to alternative designs.

Two contenders emerged from a further review. One was the reversed field pinch, an adaptation of the Tokamak design; the other was a device that had been worked on at the Oak Ridge National Laboratory since the 1960s, known as the ELMO Bumpy Torus (EBT). A hybrid between the Tokamak and mirror designs, the EBT was subsequently selected for development to a point where it can be compared directly to the operation of existing Tokamaks.

Last Autumn, four industrial consortia — headed by Westinghouse, Grumman, McDonnell-Douglas and Ebasco — produced separate plans for a 'proof-of-principle' EBT. These were amalgamated into a single design. And earlier this month the four consortia were asked to bid competitively for what has become known as the EBT-P.

The Bumpy Torus is based on a discovery made by a team headed by Dr Ray Dandl at Oak Ridge in the 1960s. When magnetic 'mirrors' produced by current-carrying coils are used at either end of a cylindrical cavity to keep plasma particles from escaping, and the plasma is heated by radio waves at the electron cyclotron frequency, a ring of electrons is found to form around the plasma at the mid-point between the two end coils.

This ring is of sufficiently high energy to keep the plasma away from the walls of the cylinder, necessary because of its high temperature. And the ring remains in place even when the end coils are inclined at an angle of 15 degrees to each other.

Putting 24 such cylindrical modules together end-to-end results in a torus. It is called 'bumpy' because the magnetic field is narrower between the mirrors than in the centre of each segment. No-one except Ray Dandl knows why it is called ELMO and he is not saying.

So far two experimental EBTs have been built at Oak Ridge (and one in Japan), and both have operated successfully according to theoretical predictions.

Operationally the EBT has two important advantages over the Tokamak, according to Dr John Sheffield, head of the Experimental Confinement Section at Oak Ridge. The first is that it operates in a steady state, rather than the pulsed mode of the Tokamak.

The second is that, without the complexity of the interlocking coils required by the Tokamak design — and the engineering difficulties caused by their magnetic interaction — construction problems could be considerably less.

Whether these advantages are sufficient to overcome the relative lack of knowledge about the EBT compared to the extensive amount already known about the behaviour of Tokamaks remains to be seen. At present EBT technology is about ten years behind; and with Congress pushing the DOE hard for the construction of an engineering test facility (ETF) for the Tokamak, it will be difficult to catch up.

Furthermore, promising results are being reported from tests with mirror confinement devices at the Lawrence Livermore Laboratory, three to five years behind the Tokamak but still ahead of the EBT. DOE officials are considering putting a request for $100 million to construct a new mirror test facility in the 1982 budget.   □

Senate approves patent changes

HOPES are high among US research universities that, following a six-year campaign, the US Congress will soon pass legislation boosting their rights to benefit directly from the results of research carried out with federal funds.

Last week the Senate passed a bill which would allow universities and small businesses, under certain defined conditions, to license any patents arising from such research. Similar measures are already under active consideration in the House of Representatives. And given the large majority that voted for the Senate measure, university lobbyists in Washington are confident that they will have a new law on the books by the end of the year.

Revision to the patent law has been a cornerstone of attempts both in Congress and by the Administration to tackle the recent drop in industrial productivity and an apparent decline in the rate of technological innovation. Both are claimed to contribute to the nation's economic problems. And both, it is argued, could be reversed by assisting the flow of research results into the market-place.

A variety of bills has been introduced into both legislative bodies over the past year. Some, such as a bill passed by a subcommittee of the House Science and Technology Committee three weeks ago, have recommended that patent rights be awarded to anyone carrying out federally-sponsored research.

The universities, however, fearful that too broad an approach might fail to win sufficient support, have put their efforts behind a more limited bill introduced by senators Birch Bayh and Robert Dole which gives patent rights to universities and small businesses, but excludes large businesses.

Six weeks ago, when the bill reached the floor of the Senate, it was threatened with a filibuster by Senator Russell Long, who claimed that liberalising the patent laws would encourage monopoly practices and discourage competition. The bill was subsequently withdrawn from debate.

When offered last Thursday, Senator Long spoke strongly against the bill. But he did not offer any amendments that might have killed the measure, and the final vote was 91 to 4 in favour, an indication of the depth of support.

Under the Senate Bill, a university will have the exclusive rights to a 17-year patent on federally sponsored research results, providing it illustrates that it has the institutional means to license the patent. The bill contains a provision that if the patent proves commercially successful, the government should be paid back for the costs of the research.   **David Dickson**

Asbestos: reductions urged

SCIENTISTS from the Occupational Safety and Health Administration and the National Institute for Occupational Safety and Health have urged further stringent reductions in the permitted exposure limits to asbestos fibres in the air.

Since 1972, the maximum permitted concentration in the work-place has been two million fibres per cubic metre in air. The scientists have now issued a report recommending that this exposure level be reduced to 100,000 fibres per cubic metre — the lowest level that can be accurately measured — and have urged a ban on all non-essential uses of asbestos.

At a news conference in Washington last week, Dr Eula Bingham, Assistant Secretary of Labour for Occupational Safety and Health, said that the agency intended to push shortly for reduced exposure limits — but refused to say whether it would endorse the study group's recommendation or a higher one.

Mind the spores!

THE US Defense Department published details last week of experiments carried out in the mid-1960s to test the New York subway system as a method for dispersing bacterial weapons.

According to the defence scientists who carried out the tests, commuters using the subway system paid little attention when they were sprayed with harmless strain of the bacterium *Bacillus subtilis* through gratings in the sidewalk, even though the aerosol clouds were clearly visible.

This lead the research workers to the conclusion that the subway system, where the draughts caused by trains would disperse the biological agents over a wide area, could prove an effective way of inflicting severe casualties on civilian populations.

Particularly effective were light-bulbs containing the test bacilli which were dropped from moving trains within the subway system. According to the Defense Department report, released after a Freedom of Information request from the Church of Scientology, the bacteria "aerosolised and dispersed rapidly by the movement of trains, penetrating stations and trains in the area and persisting there for one hour or longer."

The report says that information about the effectiveness of subway dispersion had both defensive and offensive value.

"*Forget the heroin business, Bugsy! I've something more profitable lined up!*"

Interferon sales $2 billion-plus?

ACCORDING to a report prepared by the US brokerage and investment firm Bache Halsey Stuart Shields, interferon sales could have a world wide market of $2 billion a year within three to five years. The report, summarised in *European Chemical News*, specifies three major health areas — cancer, chronic inflammations and viral diseases — in which interferon could have widespread application.

Bache estimates that in the US 5.4 million cancer patients a year could receive interferon treatment. Assuming a five-injection course of therapy at a factory price of $10 per dose, this produces a $270 million-a-year market. Subtracting $100 million a year for competing drug therapies leaves an interferon market of $170 million a year from cancer treatment.

For chronic inflammatory diseases such as arthritis, Bache estimates that interferon could capture half the market now occupied by steroid treatment. At 11.5 million patients and a course of five $10 injections the market would be around $300 million. Viral diseases are estimated to plague nine million people a year in the US. With a shorter course of three injections per treatment course sales would be worth $270 million a year. Total US sales would then be around $750 million.

Bache then estimates world wide sales on the basis of current pharmaceutical sales. In 1979, the US market accounted for 20% of the world market. Since new drugs take longer to penetrate non-US markets, Bache estimates non-US sales for interferon to be three times the US total.

The author of the report, Ronald Norman, formerly of Warner Lambert and Bache's specialist on the pharmaceutical industry, admits that some of the estimates are only guesses. In particular, the factory price of a dose could end up falling anywhere between $1 and $100 dollars a dose. "We create a rough guideline and leave it to our clients to make their own educated guesses" says Norman. (G.D. Searle in the UK has estimated that their fibroblast technique could bring the factory price down to around $2 a dose.)

Coalite health survey talks

WORKERS exposed to the toxic chemical 2,3,7,8-tetrachlorodibenzo-p-dioxin (dioxin) at Coalite and Chemical Products Ltd between 1968-1971 are to be told today the results of three surveys of their state of health (*Nature*, 6 March, page 2). But because of the make-up of the control group surveyed, interpretation of results is difficult, and the investigation may have to be repeated.

Officials of the Health and Safety Executive (HSE) are to meet the workers, and management, to give them the Executive's assessment of the surveys; but the Executive is expected to say that it is not possible to draw any firm conclusion from results so far.

Two of the studies — those on the blood chemistry and immunology — detected differences between the dioxin-exposed men and the control group; but the third study on chromosome changes reported no differences between the two. The study of blood chemistry showed changes in total blood cholesterol and high density lipoprotein cholesterol levels in the exposed workers. And the immunology study reported reduced levels of two immunoglobulins, IgD and IgE in a significant proportion of them.

However, the control group used was not properly matched with the exposed group, making comparison between the two difficult. The control group included management staff undergoing lipid screening at the time.

One HSE official hinted that something might be salvaged from the studies when the raw data had been examined but admitted that the investigation may have to be repeated.

Even though the HSE persuaded Coalite to arrange the studies two years ago, it did not receive the results until a few weeks ago. This delay was due in part to a belief within the HSE that it lacked the necessary powers to compel Coalite to disclose the findings.

An Executive spokesman has now said that the HSE does have the legal powers under Section 27 of the 1974 Health and Safety at Work Act to serve a notice on any individual to disclose information which the Executive requires. **Alastair Hay**

France

Cap la Hague restarted

THE accident at the reprocessing plant at Cap la Hague which resulted in the total loss of electric power a fortnight ago (*Nature,* 24 April, page 653) may have been the result of circuit overloading according to the CFDT, the main union representing nuclear workers at the plant. A spokesman for the union told *Nature* that some of the power supply equipment was 15 years old and had been initially designed for the reprocessing of low activity spent fuel only. However, high activity fuel was now reprocessed there although the plant had not been fully upgraded to cope with the increased current this demanded.

According to reports in the *Guardian*, Cogema decided to restart operations last week after receiving clearance from the Ministry of Industry. A spokesman for Cogema had said that radiation levels were acceptable. Workers at the plant, however, were worried that several parts of the plant were still highly contaminated. According to the CFDT spokesman, an expert who had visited the plant had recommended that it should not be restarted. The director however, decided to go ahead.

The union met at the end of last week to discuss how to react to Cogema's decision to restart operations even though full repairs have not been carried out. In the absence of any detailed technical report, no agreement on what action to take was reached except that the union's concern over the decision should be expressed.

Cogema's desire to restart only eight days after the accident is seen as a move to reprocess spent fuel already stored at the plant to make room in the storage ponds for a consignment of Japanese spent fuel awaiting shipment in the UK. Workers believe that as soon as this backlog is cleared, the plant will be closed in two to three weeks time for full repairs.   □

Mozambique

The politics of African archaeology

THE opening of a new museum at Manyikeni in Mozambique marks a change in the presentation of archaeology in Southern Africa.

At issue are the "Zimbabwes" — a chain of 150 ancient settlements characterised by central stone-walled enclosures spread across Mozambique and what is now called Zimbabwe. White settlers in Rhodesia argued that the stone walls were Egyptian temples built by the Queen of Sheba, while the Portuguese in Mozambique opted for their construction by mythical Lusitanians.

As early as 1905, the British Egyptologist, Randal McIver, established that not only were the ruins not Egyptian, but that they were built in the past 1000 years, and thus necessarily by local, black, people. Later all other archaeologists agreed. But that answer was totally unacceptable to the white settlers, who stuck by the Queen of Sheba.

The advent of scientific archaeology made this position increasingly untenable. The first carbon tests in the 1950s suggested that Great Zimbabwe, after which the country Zimbabwe has taken its name, was built around 1000 years ago. (Great Zimbabwe was the most striking of these settlements and with a population of 10,000, must have been the largest city in southern Africa at its peak in 1400.)

A guidebook to Great Zimbabwe published in the early 1960s contained the carbon dates and dismissed the Queen of Sheba explanations. In the late 1960s and early 1970s much better carbon dates were

Manyi Keni . . . first exhibition on basic data

produced for Great Zimbabwe, but the then Rhodesian government not only refused to permit them to be displayed, but ordered the removal of all dates from the Zimbabwe displays in museums. And the guidebook was allowed to go out of print. In 1975, when a new guidebook was being written, the government ruled that carbon dates could not be included.

In Mozambique the attitude was different. The Portuguese simply never excavated the Zimbabwes, so there was no data to contradict the Lusatanians.

In 1975, however, after independence in Mozambique one of the Zimbabwes — Manyikeni, 50 km west of Vilanculos was excavated. The work has been done by a Mozambican archaeologist, Joao Morais, and two British archaeologists, Peter Garlake and Paul Sinclair. Both Garlake and Sinclair had worked at Great Zimbabwe, and both quit over the supression of scientific data.

Carbon dating, done free of charge by the University of Rome, shows that Manyikeni was occupied from 1250 to 1750, and that the walls were built around 1450. The stone walls, about two metres high, and similar to English dry stone walling, made an enclosure inside which about five families lived. The new museum displays show carbon dates and detail the

recent excavations and scientific stories.

Several scientific techniques have been brought to bear on the site, some for the first time. One is stratified sampling, in which the site was first divided into 20 metre by 20 metre squares, and then four randomly selected one metre by one metre trenches excavated within each of the larger squares. This gives a better overall picture of life in the settlement than just by digging at "likely looking" spots. Until the early 1970s, all the excavation was done inside the walls. But then it was realised that the bulk of the settlement was actually outside. The area outside is too large to excavate completely and stratified sampling is the only sensible way. Manyikeni is the first Zimbabwe to be extensively excavated outside the walls.

The excavation of this site represents one of Mozambique's first efforts to illuminate its history before the colonists arrived. It also reflects Mozambique's attempt to popularise science. The excavation was done by local people, under the supervision of the professional archaeologists. And the musuem is primarily intended to teach local people their own history. Yet it also represents the first exhibition in Mozambique or Zimbabwe of some basic scientific data.

Joseph Hanlon

NEWS IN BRIEF

Three Mile Island health effects

HEALTH officials in Pennsylvania have discounted recent claims that increased infant mortality in the area around the Three Mile Island nuclear power plant was due to the accident at the plant last March. They point out that the area also experienced an increase in total births, and that the mortality rate therefore remained constant.

However, they have also reported a "surprising" degree of anxiety among residents living near the reactor, with significant increases in the use of tranquillisers and sleeping pills. Nearly half of 1,000 people interviewed in January who live within 10 miles of the plant reported physical symptoms of stress, ranging from headaches and diarrahoea to a loss of appetite and the appearance of rashes.

The survey, conducted by behavioural scientists at the Hershey Medical Center of Pennsylvania State University, also found that nearly 13% of those living within five miles of the Three Mile Island plant had become anti-nuclear activists. Dr. H. Arnold Muller, the State Secretary of Health, called this figure "very significant."

Drilling Project faces big cut

THE US House of Representatives Science and Technology committee has proposed that federal support for the first year of a massive Ocean Margin Drilling Project, to be sponsored jointly by the National Science Foundation and private oil companies, be reduced from $5 million to $500,000.

The $5 million recommended by the Carter Administration in its revised budget proposals last month had already been reduced from $10 million included in the original NSF budget proposal in January. However, the Senate Health and Human Resources Committee, voting last week on the NSF appropriations request for the fiscal year 1981, is proposing restoring funding for the project to about $9 million — which provides room for an appropriate compromise.

MIT raises $250 million

THE Massachusetts Institute of Technology announced last week that it has successfully raised $250.2 million — $25 million above its target figure — in a five-year fund raising campaign.

About a quarter of the total will go to endowing new faculty positions, and an equivalent amount to new teaching and research facilities, including the construction of the new Whittaker College of Health Sciences. The remaining funds will go to supporting new programmes and other uses.

MIT is also expected to announce this week a major agreement with the Exxon oil company to support basic combustion research at the institute.

Chojecki held

MIROSLAV Chojecki (above), a young Polish physicist and human rights activist, was recently arrested under a "procurator's sanction", which empowers the police to hold him up to 90 days without charge or trial.

Chojecki was formerly a research assistant working for his PhD at the Warsaw Nuclear Research Institute. During 1976, he was a frequent observer at the trials in Radom of workers who had taken part in the June demonstrations against food price rises. In October 1976 he was dismissed from his post and has not since been able to find professional employment. He has recently been active in "Nowa", the "independent" (i.e. underground) dissident publishing group.

In an "open letter" written shortly before his arrest, Chojecki stated that since his first arrest on 30 September 1976, he has spent about five months in detention (equivalent to one day a week). His flat has been searched 15 times ("once a quarter") and his person 80 times ("once a fortnight"). On only three occasions was a search warrent issued.

Items confiscated from him range from a text book of Fortran programming to a jar of curry powder (thought by the police to be radioactive isotopes), cuttings from the official Polish press, three tins of imported meat and the contents of his waste-paper basket. He has been fined on a number of occasions for petty offences a total of 19,000 zl. (£350).

It is understood that he is likely to be charged in the near future with being in unlawful possession of printing equipment.

Burbridge to head astrophysics unit

DR Margaret Brubridge has been appointed to direct the new Centre for Astrophysics and Space Sciences at the University of California in San Diego. The centre has been organised to coordinate the scientific activities of several groups which carry out research in astrophysics and space science in three university departments — physics, electrical engineering and computer science. Also included in the regrouping of space science disciplines is the cosmochemistry group in the chemistry department. The centre will house under one roof high energy astrophysics, solar physics, optical and infrared astronomy, the Faint Object Spectrograph (Space Telescope) team, magnetospheric physics and radio astronomy. Laurence E. Peterson and Elden C. Whipple will be associate directors of the centre.

CND marches again

The UK Campaign for Nuclear Disarmament (CND) has organised a major demonstration to protest the installation of the Cruise missile on British soil. The demonstration will begin in Oxford and participants will march 18 miles to the US Air Force base in Upper Heyford, an expected site for the Cruise missile.

An internationally known organisation for the expression of grass roots opposition to nuclear war in the early 1960s, CND is undergoing a revival in the UK at the present time. "Judging from our mail and our discussions with the large number of volunteers that have come forward, people now are concerned about the international situation, particularly Carter's irresponsibility in Iran, the government's attempt to revive civil defence, and the increasing cost of the military budget at the expense of social services," says Caroline Coles of CND.

Monkey business

The Indian Commerce Minister, Z. R. Ansari, recently told Parliament that there was no proposal to lift the export-ban on rhesus monkeys, though several representations had been received from importing countries. The ban was imposed two years ago by the Janta Government following revelations that rhesus were being used in neutron bomb testing. The US drug industry is trying to convince the Indian government that the ban has adversely affected the introduction of several new drugs and even caused shortage of polio vaccine, which is sold in large quantities in India.

FEATURES

A social worker makes a health call on a Brazilian family . . . but will the bureaucratic machine get in her way?

Brazilian paralysis: the real disease

AFTER being invited to work in Brazil by the country's Minister of Health in January, received with official honours by the President of the Republic, and feted as a Nobel prize-winner (which he is not), Dr Albert Sabin, developer of the oral anti-polio vaccine, has left the country a disillusioned man. The muddle, inefficiency and sheer obstructiveness of the Brazilian Health Ministry proved too frustrating for Sabin to bear, and he has returned to his Charleston, Carolina, laboratory without taking leave of Health Minister Valdir Arcoverde.

"In truth," he commented, "it is difficult to take leave of a man who does not let himself be approached."

By Sabin's account, the history of Brazil's approach to its regular epidemics of polio is one of garbled statistics and

---

Health care in Brazil is not simply a matter of science and sound management. It is a matter of politics. **Maurice Bazin** reports on a case history — the 'Sabin episode'

---

official indifference to the plight of the thousands of children who still contract the disease. And he has said as much in a letter to President Figuereido.

"Bureaucratic problems of various types do not permit that this work be properly developed," he complained. "I must emphasise to your Excellency that this

same bureaucracy was responsible for the failures in combating poliomyelitis in the past, and, as for the present, I have strong reasons to doubt that the next attempts will be successful."

The President has not replied.

The first major problem Sabin encountered during his two-month stay in Brazil was the impossibility he found in obtaining an estimate, however approximate, of the scale of the polio problem over the preceding ten years.

He pointed out to the Health Ministry that statistics published during that period by the Institute of Geography and Statistics (IBGE) on the one hand and the Health Ministry on the other differed by factors "at times as high as 60 and 170". Brazil's reports to the World Health Organization showed 15,000 cases of polio per year from
> ❛Brazil needs a national vaccination campaign. However, this task will continue to come up against bureaucratic structures and unreliable sectors. There is a lot that can be done, must be done, and that is not being done❜
> — Albert Sabin

1969 to 1972 followed by an abrupt decline to 2,100 cases per year from 1973 up to the present. Could this effect be the reflection of a national immunization campaign carried out in 1971? Looking through the records, Sabin found out that the high figure came from the IBGE whose data was transmitted to WHO up to 1972, while the low figure came from the Health Ministry's own statistics. The apparent drop corresponded to no more than the switch in data sets. Furthermore, since 1975, IBGE had been forbidden to supply any more statistics about polio.

"Nobody lied or manipulated the data," he said, "but the whole truth was not told. The officials of the Health Ministry are guilty of breach of duty because they did not inform the public about the change from one set of statistics to another. And still now they continue to give out improper information to WHO."

While working with a local vaccination campaign Sabin heard that his proposal for obtaining realistic statistics about polio incidence from a survey of school children was considered by the ministry to be "of dubious statistical value", although it had been approved by the minister six weeks earlier. But he organized a local statistical evaluation of the incidence of polio for 1969-72 and 1973-76 by looking for sequels of paralysis in children 10 to 11 years of age and six to seven years of age respectively in the Federal District around Brasilia today.

He enlisted the participation of local doctors and school personnel and found 57 cases of clear paralytic sequels in a sample of 25,000 children. From the detailed data, which represents a minimum evaluation, he could conclude that the IBGE statistics for these periods were closer to reality than those of the Health Ministry, which were at least five times below the true level.

Sabin's own data, however, are certainly still very much below a realistic estimate of the number of polio cases because they rely upon a sample of children presently in schools. In the poor districts around Brasilia many children do not go to school, and physically maimed children are often beggars in the streets and not registered school children. The only technical comment that minister Arcoverde made after Sabin made his results public at the end of March was:

"Dr Sabin is an excellent epidemiologist, however, he is no a statistician." To which Sabin replied publicly: "The Minister says that the ministry's statistics are satisfactory; I say it's completely untrue."

In the course of his investigation in the Federal District, Sabin found out that 88% of the children had contracted polio before two years of age and 45% before reaching one year, and that parents only knew of it when they noticed that their child had difficulty in starting to walk. As he went to the slum satellite cities of the Federal District and around Brasilia, diagnosing the origin of children's physical deformities, he could remember that official statistics reported no polio cases outside the capital proper during 1976, 1977 and 1978. Today, he noted, the industrial suburbs of the city of Sao Paulo have a polio incidence five times higher than the city proper.

Using the weekly reports of polio cases for different states of Brazil, Sabin found that epidemics appeared to last much longer than in European countries, at times up to six months or more. However, looking with care at the geographical origin of the reported cases, he could prove that an epidemic propagates across a state and lasts the customary three to four weeks in each locality. He therefore proposed a plan of action to stop the ongoing epidemics in the state of Santa Catarina in the south of Brazil, which he had been called to help control in January. The state's health secretary mobilized thousands of school teachers, policemen and community members to carry out a massive vaccination in one day in the communities immediately in front of the wave of contamination.

"We learnt that we could not do a vaccination in one day because the statistics about the number of children in the community were wrong. In some places we had vaccinated 110% of the children! But by the second day we reached almost all children, with teachers going door to door all day in the hot sun." Three weeks later the last hospital admittance for polio was registered in Florianopolis, the state capital.

Open conflict between the scientist and the minister never occurred. Health bureaucrats, comfortably installed in their futuristic buildings in Brasilia, continued smiling to the scientist, but stopped answering his memoranda. In a mixture of efficiency and idealism, Sabin would announce in a memo that there were no steel lungs available to save children with affected respiratory muscles outside the cities of Rio and Sao Paulo, indicate how to recover the huge lungs which were used in the US before vaccination existed, and where to acquire new plastic models. He included in the memo the telephone numbers of the manufacturers.

"Unfortunately, these recommendations dissolved away in bureaucratic side tracts" he wrote in his open letter to the President of the Republic.

At the same time, the Society of Pediatrics of Brasilia declared that "vaccination campaigns are never executed adequately for administrative reasons mixed with politics."

Sabin's letter to the President added: "Brazil needs a national vaccination campaign, organised in a highly efficient way and conducted every year. However, this task will continue to come up against bureaucratic structures and unreliable sectors. Just like in military operations, inexact information about enemy forces can bring about disasters; the same occurs when you face an epidemic disease . . . I have met in Brazil dedicated and competent men and women, capable of carrying through this task. I accompanied them in Goiás, Santa Catarina, Paraná and the Federal District, and I personally observed the contrast between their work and that of the official bureaucracy . . . There is a lot that can be done, must be done, and that is not being done."

Despite Sabin's efforts the fundamental social problem remains of how to protect a whole population through a lasting organized effort of routine vaccination. To contribute to this effort was part of Sabin's plans for 1980. It is now very doubtful that anything will come of it.

For saying aloud what officials in power were not interested in hearing, Sabin is now back home, and his data on polio in Brazil will be published in English-speaking professional magazines only. The president of the Society of Medicine and Surgery of Rio has compared the "Sabin episode" to the case of Galileo. □

CORRESPONDENCE

Expanding on Parkinson's Law

SIR, — Parkinson summarised his large experience of administration in the law that Work Expands So As To Fill The Time Available For Its Completion (C.N. Parkinson, *Parkinson's Law*, 1958). A corollary of this law, that the proportion of administrators within a public organization tends to increase with the size of that organization, has been confirmed by empirical observation (R. Moss, *Nature*, 273, page 184, 1978). Schumacher in *Small is Beautiful* (1974), challenged conventional wisdom by showing that large, centralized organizations are often less efficient than small ones, and Moss made observations on the staffing structure of the Natural Environment Research Council (NERC) which showed that component bodies of NERC in which the administration was dispersed amongst many addresses have fewer administrators and other support staff than other, more centralized bodies of comparable size. Further, J. Flux's detailed study of the Ecology Division of the New Zealand Department of Scientific and Industrial Research (in *Focus on Social Responsibility in Science,* 1979), showed that the production of scientific papers per man decreased as the organization increased in size.

These scientific observations have not been followed by a reorganization in the administration of scientific research. Colleagues have suggested that this is partly because the original empirical observations were not accompanied by a theoretical model. Such a model is therefore presented.

Consider the situation in which we have a number W (W = 4 in the example of the figure) of individuals or groups of individuals doing a certain amount of work such as making scientific discoveries or collecting tax. The simplest possible situation is that each individual worker gets on with his job, pausing occasionally to speak with colleagues, answer letters and arrange for the office windows to be cleaned. As W increases, such primitive liaison techniques may become less effective and an administrator may be appointed.

In the model, the administrative workload of an individual is a function of the number of people with whom he communicates. This is the number of lines of communication l, as may be seen in the figure and, for brevity, is subsequently referred to as 'workload'. In stage one of the model each speaks with each of his colleagues and also with the outside world

$$l_{wi} = W$$

where l_{wi} is the workload of worker i.

In stage two of the model, when the administrator is newly appointed, each worker continued to speak with other workers, but also communicates with the administrator. Of course a 'worker' in this model could as easily be a constituent organization within an 'umbrella' organization such as the Agricultural Research Council (ARC), the Medical Research Council (MRC) or NERC. In stage two

$$l_{ai} = W + 1$$

and, as before

$$l_{wi} = W$$

where l_{ai} is the workload of administrator i (of course the suffix $_i$ is redundant at this stage, but it becomes useful later).

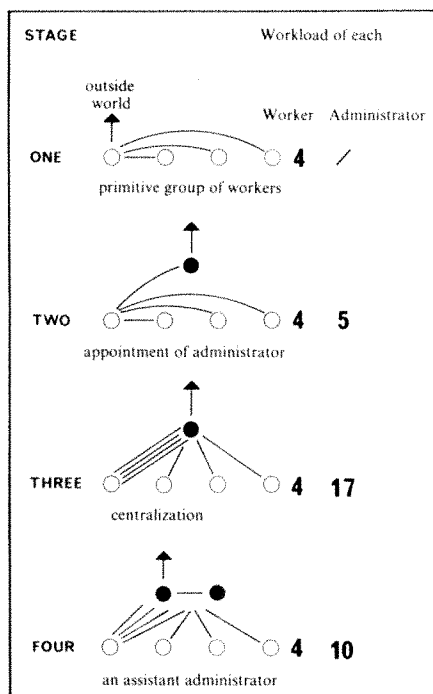
When the excitement of reorganization has settled into the humdrum of routine, the administrator has an idea which many readers will recognise. "It is grossly inefficient for all of you (W) to be wasting time liaising both with each other and with me (a$_i$). Let us re-organize our lines of communication so that you all communicate through me". This is


Figure. Illustrating the number of lines of communication (administrative workload) between members of an organization containing four workers, as it passes through the four stages of Parkinson's Progression.

Note. For clarity, lines of communication for one worker only are shown — lines of communication for the others follow an identical pattern.

stage three in the figure. "That will be much more efficient". Efficiency, of course, is only one objective of this course of action. Lust for power is an important motivation and the concept of 'accountability' is often pressed into use at this stage.

In stage three the workload of each worker remains the same, although cooperation amongst them is slowed down by the length of time that their messages lie on the administrator's desk. But the workload of the hard-pressed administrator now rises sharply as he grapples with all the matters that had previously been the subject of direct communication between workers. As well as communicating directly with W and the outside world, he now passes minutes to and from all the W.

$$l_{ai} = W^2 + 1$$

and, as before

$$l_{wi} = W$$

This situation is intolerable: in our example it can be seen that the administrator's workload has increased by more than three times, without any increase in the number of workers. This is the effect of centralization. In desperation our administrator applies for assistance. This is stage four where efficient co-operation amongst administrators gives

$$l_{ai} = \frac{W^2}{A} + A$$

and, as before

$$l_{wi} = W^2 + A$$

A being the number of administrators. Our exemplary administrator in the figure has thriftily indented for only one assistant and so the number of administrators has now doubled, but the workload of each is

nonetheless double what it was in stage two. Both administrators are working very hard, as evidenced by the large number of minutes processed since stage four came into operation. More assistants may well be needed to cope with the increased workload.

Our two administrators may well assume that the more colleagues they have, the smaller will be their individual workload. This is true up to a point, the point being four administrators to four workers in our example Beyond that number, however, l_{ai} increases again as the administrators spend an increasing proportion of their time sending minutes to each other. In general, the minimum workload per administrator $l_{ai_{min}}$ is attained when A = W, that is when the proportion of administrators in the organization is 50%. This may well be the 'maximum ratio' referred to by Parkinson, beyond which the proportion of administrators is unlikely to increase. It is notable that the maximum percentage of non-scientific staff in any of the component bodies of NERC is exactly 50%.

At this point, let us turn our attention to the next rank up in the hierarchy, the chief administrator c_i who appointed our administrators in the first place and to whom they are responsible. His workload will increase as A increases. Initially, his workload will bear the same relation to A as that of A did to W. But, as A increases, he may decide that further centralization is called for in pursuit of increased efficiency . . . with the inevitable consequence that stages three and four repeat themselves at this and possibly higher levels in the hierarchy.

Parkinson's Law has long been regarded as a joke by administrators who know that they work very hard. But what do they work hard at? The writer's experience is that questions such as this, pursued in the course of objective scientific analysis, are sometimes resented by administrators of scientific organizations. The model presented here shows simply and not unrealistically that the effects of centralization are to increase the amount of information that an administrator processes, whilst decreasing the proportion of workers in the organization. Had this model been available and accepted by those in authority some years ago, the re-organization of, for example, local government and the National Health Service, accompanied by decreased standards of service and increased administrative staffs, might not have occurred.

A problem with the model is the simplified assumption that all lines of communication are equivalent in the amount or work that they represent. A logical step next is to test the robustness of this approximation by making measurements of the amount of work per line of communication in the field, factory, office or laboratory.

The principles that the number of administrators tends to increase irrespective of the amount of external work done by an organization, due to Parkinson, and that increased centralization is accompanied by decreased effectiveness, pointed out by Schumacher[2], were empirical and inductive observations made by wise and experienced men. I provide a deductive and quantitative basis for these classic observations, a step towards management by reason rather than intuition.

Yours faithfully,

ROBERT MOSS

NEWS AND VIEWS

The third category of extraterrestrial material

from A.E. Fallick and C.T. Pillinger.

OVER the past ten years two new sources of extraterrestrial material have led to rapid advances in our understanding of the chemistry of the cosmos. The first, of course, was the return of samples from the Moon by the Apollo and Luna spacecraft. The second was the discovery of early condensate-type inclusions in the Allende meteorite, which were found to have anomalous isotopic abundances of various elements and are believed by some workers (see *Nature* 283, 813; 1980) to be older than the Solar System itself.

Now a third class of extraterrestrial material, consisting of the "Brownlee particles" collected in the stratosphere by specially adapted U-2 aircraft, and meteor ablation debris scavenged from the ocean floor (see *Nature* 279, 20; 1979), may be added to the above. As common meteors have orbital parameters indicative of a cometary origin, the new material is of particular interest because it is generally held that comets represent the most primitive sample of the Solar System. Some arguments (for example Napier & Clube *Nature* 282, 455; 1979) have been presented that comets may even be planetesimals temporarily captured during passage of the solar system through the spiral arms of the Galaxy. If this view is correct cometary material becomes of immense importance, for it is then possible that it may be rapidly cooled, explosive debris from highly evolved, massive stars.

Last year, Ganapathy and Brownlee (*Science* 206, 1075; 1979) definitely identified two stratospheric particles as micrometeorites by comparing volatile and nonvolatile trace element concentrations with those of CI chondrites, reckoned also to be primitive solar system material. Studies on single grains less than about 40μm in diameter are not easy but results reported at the recent Lunar and Planetary Science Conference* show studies of stratospheric and deep sea material have great potential. Don Brownlee and colleagues (Seattle and Caltech) have recognised unmelted carbonaceous chondrite, CI and CM materials in deep-sea sediments, and P. Fraundorf and co-workers (St. Louis) have demonstrated the presence of the "cosmic" 10μm feature in the optical absorption spectrum of

*The XI Lunar and Planetary Science Conference was held at the NASA Johnson Space Centre, Houston, Texas, March 17-21, 1980.

stratospheric particles. B. Hudson and co-workers also of St. Louis, succeeded in refining experimental techniques to allow them to determine He, Ne and Ar concentrations in a sample of thirteen Brownlee particles, each typically 10μm across and with estimated total weight of around 10^{-8} g. They found a $^{20}Ne/^{36}Ar$ ratio of 9 ± 3, which resembles the ratio for lunar soil fines (~7) more than it does the terrestrial ratio (~0.5). Assuming the gases to be solar in origin, the time taken to accumulate the Ne and Ar could be the surprisingly low figure of 10-100 years, based on current estimates of solar wind fluxes. As microparticle analysis seems likely to become more efficient and with proposals for a European Space Agency mission to the comet Halley in 1985-6 still active, perhaps the 1980's will be the decade of cometary science.

Work on the first two categories of extraterrestrial materials continues to become much more refined. New studies of solar noble gases in lunar regolith minerals were unveiled by Peter Signer (Zurich). His group have measured ^4He or ^{36}Ar and ^{38}Ar in some 90 individual plagioclase grains and failed to find evidence for whole grain saturation in either ^4He or ^{36}Ar. A search for microscopic saturation is under way using track density studies; the absence of such saturation as a common feature would allow mean noble gas abundances in the ancient solar wind to be inferred from minerals exposed at the appropriate time. M. Thiemans and R. N. Clayton (Chicago) are studying $^{15}N/^{14}N$ in the Apollo 17 deep drill core in an attempt to reconstruct the history of the supposed solar wind nitrogen isotope variations. "Nitrogen is the newest member of the family of noble gases" quipped Clayton.

Dieter Heymann (Rice, Texas) attempted to develop a plausible Xe isotope stratigraphy for a massive star immediately prior to, and after, the supernova explosion. Because of the paucity of observational constraints such a model is difficult to assess, but Heymann pointed out the remarkable agreement between the Xe isotopic profile of the explosive products and the well-defined Xe components in carbonaceous chondrites. More stringent testing will come from the application of the model to isotope profiles of other elements.

Sam Epstein (Caltech) has devised a technique whereby $\delta^{17}O$ may be estimated to $\pm 0.5\%$ from $\delta^{18}O$ and $\delta^{13}C$ determinations on CO_2. This obviates the necessity for running O_2 in the mass spectrometer. The procedure was checked by analysing three inclusions from the Allende meteorite and then applied to investigating reactions involving excited species of oxygen compounds. G. Arrhenius and others have suggested that similar reactions may produce strongly nonlinear kinetic isotope fractionations (see *Nature* 279, 20; 1979); however, in his preliminary experiments, Epstein found no evidence of this, despite a spread of 100% in $\delta^{18}O$. An important step forward in understanding the stable isotopes of H, C and N in extracts from meteorites was reported by F. Robert and colleagues, also from Epstein's laboratory at Caltech. Using a combination of solvent extraction, HF hydrolysis and stepwise heating techniques, they detected isotopic differences in C and N between different organic components in CM chondrites. Deuterium associated with insoluble organic fractions is enriched by 90% (sic) compared to inorganic nitrogen, and decoupling from ^{13}C and ^{15}N enrichment is suggested. Interest now centres on whether equilibrium-type mechanisms of Fischer-Tropsch-type reactions will be successful in accounting for such observations, or if (as seems more likely) different source materials for the various components are required.

Nature still continues to spring surprises on those investigating the host phases of rare gases in meteorites. The Chicago-Berkeley controversy over the identification of the various carriers took a new twist with the report by Roy Lewis and co-workers (Chicago) of no fewer than five different forms of carbyne in Murchison and Allende. Carbynes are a series of linear polymorphs of carbon with alternating single and triple bonds; they are the stable low pressure forms above 2600°K and have recently been suggested by Webster (*Mon. Not. Roy. Astron. Soc.* in press) as candidates for interstellar dust and stellar

A.E. Fallick and C.T. Pillinger are in the Planetary Sciences Unit, Department of Mineralogy and Petrology, University of Cambridge.

condensates. U. Ott (Berkeley) has made a detailed study of colloidal separates from an Allende acid residue with the aim of unravelling more clues to the enigmatic phase Q (defined operationally as a residue fraction soluble in oxidising acids). His results are consistent with Q being carbonaceous rather than an inorganic mineral. Several years ago, Srinivasan *et al.* (*J. geophys. Res.* **82**, 762; 1977) compared Reynolds' first measurements on xenon in meteorites to the opening of Pandora's box: perhaps the pace of advance now encourages us to believe that before long the reluctant Hope will be coaxed out of the box also.   □

Discrete Σ-hypernuclear states

from R. H Dalitz

LAST summer, an experimental group headed by B. Povh, Max-Planck- Institut für Kernphysik, Heidelberg and working at CERN, reported to a conference 'held at Vancouver, the observation of well-defined peaks in the pion spectra following the $K^- \to \pi^{\pm}$ reactions at $0°$, for K^- mesons of momentum 720 MeV/c incident on ^{7}Li, ^{9}Be and ^{12}C targets. These peaks are in the part of the spectrum which corresponds to the production of a Σ-hyperon, and the widths reported for these discrete states are of order 10 MeV. These narrow Σ-hypernuclear states were not anticipated by theoreticians but turned up in the course of a study of the highly-excited Λ-hypernuclear states produced in the $K^- \to \pi^-$ reaction.

The hyperons Λ and $(Σ^-, Σ^0, Σ^+)$ are well-known. The Σ-hyperons are about 75 MeV heavier than the Λ hyperon and have the same strangeness quantum number, $s = -1$. $Σ \to Λ$ reactions, of the type $Σ^- + p \to Λ + n$, are exothermic and allowed by all the selection rules governing strong nuclear interaction processes. This led to the general expectation that a Σ-hyperon in contact with a nucleus would transform to a Λ-hyperon in a time of order 10^{-24}s. Since this is less than one-tenth of the time taken by a hyperon to travel across a nucleus, it appeared most unlikely that discrete quantum states could exist for a Σ-hyperon within a nucleus. All of our experience of Σ-hyperon processes observed in nuclear emulsion and in bubble chambers was consistent with this view. For example, the study of X-rays emitted by $Σ^-$-hyperons in atomic orbits around nuclei showed that $Σ^-$-hyperons coming to rest in condensed matter are captured by the nucleus predominantly from high-lying orbits. As the $Σ^-$-nucleus system cascades down through its atomic levels (which are due to their Coulomb attraction), emitting a photoelectron or X-ray at each step, the capture reaction $ΣN \to ΛN$ occurs as soon as there is any appreciable overlap of the $Σ^-$ wavefunction with that of the outer nucleons of the nucleus. Thus, the nuclear capture processes take place on the extreme periphery of the nucleus, and the yield of X-rays due to transitions between the inner atomic orbits is low relative to those for

R.H. Dalitz is Royal Society Research Professor in the Department of Theoretical Physics, Oxford University.

the outer orbitals since few $Σ^-$ hyperons escape nuclear capture and reach the inner levels.

The $K^- \to \pi^{\pm}$ reactions studied in these CERN experiments are termed "strangeness exchange reactions". The strangeness of the meson increases by $\Delta s = +1$, and the strangeness of the target nucleus (initially $s = 0$) becomes -1, since total strangeness is conserved by the strong interactions. Thus the final nuclear system reached includes one hyperon. These reactions have a special feature, due to the fact that the mass difference $(m_K - m_{\pi}) \simeq 355$ MeV is greater than the mass difference $(M_Σ - M_N) \simeq 255$ MeV. In this case, the $N \to Σ$ strangeness exchange reaction can take place for a K^- meson at rest and in contact with nuclear matter. For non-zero incident momentum $p_{\bar{K}}$, we confine attention here to pions emitted at $0°$ to the K^- momentum since this configuration gives the least momentum transfer q to the target nuclear system. As $p_{\bar{K}}$ increases from zero, this momentum transfer falls until a "magic momentum" p_0 is reached at which the momentum transfer q is zero. As $p_{\bar{K}}$ rises further, the momentum transfer q increases from zero, but it rises only to 290 MeV/c, even in the limit of infinite incident momentum.

For the $0°$ reaction, the strangeness exchange process allows no spin flip for the target nucleons. At the magic momentum $p_0 \simeq 280$ MeV/c, the orbital states in the initial nucleus are preserved in the final hypernuclear state, since the momentum transfer $q = 0$. The reaction then consists of replacing a nucleon by a Σ particle, with precisely the same wavefunction; the amplitude for this replacement receives coherent contributions from all the nucleons of the target and the cross section is correspondingly enhanced. There has already been much experience with these coherent transitions for the case $N \to Λ$, where $p_0 \simeq 530$ MeV/c (Povh *Ann. Revs. Nucl. Phys.* **28**, 1; 1978). In practice, it has become evident that this coherence extends only to the nucleons in a given shell, but the coherent transitions leading to final Λ-hypernuclear states with the same spin-parity J^P as the target nucleus do stand out clearly in the $0°$ pion spectrum, even for incident K^- momentum $p_{\bar{K}} = 720$ MeV/c, for which we have $q \simeq 40$ MeV/c. For p-shell nuclei, which have had the most

detailed study, the Λ-hypernuclear states reached in this way are necessarily excited states. Substitution of a 1s neutron by a Λ hyperon leaves a hole in the 1s neutron shell; substitution of a 1p neutron by a 1p Λ hyperon leaves the V particle far above its 1s ground state. These remarks also apply to the Σ-hypernuclear states coherently produced by the strangness exchange transition $N \to Σ$. The important difference was the expectation that the strong absorptive reaction $ΣN \to ΛN$ would cause these states to be so broad as to be unobservable in the pion spectrum. The CERN experiments have now shown that this expectation does not hold for all Σ-hypernuclear levels; some discrete levels do exist, even if only for a time of order 10^{-22}sec.

First, it is useful to remark that some particular Σ-hypernuclear states are expected to be semi-stable, i.e. to have lifetimes of order 10^{-11} sec., comparable with the lifetime for free $Σ^-$ hyperons, if they exist as bound states. The clearest examples are the systems ($Σ^-$ + neutrons); charge conservation does not allow any transition $Σ^- \to Λ$ on a neutron since there is no nucleon state with negative charge. Despite much searching, no empirical evidence has been found for any bound states of this type, nor for the charge-symmetric systems ($Σ^+$ + protons).

Gal and Dover (*Phys. Rev. Lett.* **44**, 379; 1980) have now made calculations intended to demonstrate that the existence of some discrete Σ-hypernuclear states is compatible with our other knowledge of hyperon-nucleon interactions, and to identify the structure of these states. The strength of $ΣN \to ΛN$ absorption is taken from experimental data, as interpreted in terms of theoretical hyperon-nucleon potentials. The rate used is $(v\sigma_{abs}) \simeq 19$ mb, the average being over the nucleon momentum distribution in a nucleus, v denoting the Σ-N relative velocity. The Σ-nucleus interaction can also be viewed as a "cloudy crystal ball", i.e. a potential with the nuclear shape ϱ (r) and a complex strength $(U + iV)$. Then V is proportional to $(v\sigma_{abs})$ and therefore known. U has to be left as a free parameter, whose value can be determined later from the energy observed for an identified Σ-hypernuclear level, but it is not of importance for the total absorption rate. The solution of the Schrodinger equation for the Σ-hyperon in this potential will give a complex energy value $E = (\varepsilon - i \Gamma/2)$ for each orbital (n,l), the imaginary part Γ (n,l) being the width for this orbital.

For heavy nuclei, the Σ hyperon sees "nuclear matter" and the width Γ does not depend strongly on the orbital (n,l), when this lies dominantly within the nucleus. Typical values for Γ are then in the range 20-30 MeV, a width large relative to the spacing of the energy levels so that the individual levels cannot be distinguished.

For light nuclei (^{12}C and lighter, say), it is

important to take into account the isospin- and spin-dependence of the ΣN interaction. For ΣN isospin 3/2, there is no absorption possible, since the ΛN state has isospin 1/2; the absence of nuclear absorption in a state $(\Sigma^- + \text{neutrons})$ is a particular example of this situation. Also, we believe that, for low ΣN energies, the $\Sigma N \rightarrow \Lambda N$ absorption rate is much less in the singlet spin state than in the triplet spin state. Hence the observation of a narrow Σ-hypernuclear width calls for a configuration where (i) the nucleon density is small where the Λ-particle is, (ii) the isospin-3/2 ΣN interactions have a high relative weighting, and (iii) the singlet ΣN interactions have a high relative weighting, and (iv) its formation is coherent. For ^{12}C target, this state is identified by Dover and Gal to be the isospin-3/2 particle-hole state with structure $((1p)_N^{-1}(1p)_\Sigma)_{J=0}+$, its calculated width due to absorption being about 5 MeV. The isospin 3/2 state can be formed in both reactions $K^- \rightarrow \pi^\pm$, and this is also the case empirically. No other state considered has width much less than 20 MeV and no others are claimed empirically, at present. The isospin-1/2 state with the same structure has a calculated absorption width of about 18 MeV.

Two Σ-hypernuclear peaks were seen for ^9Be target. The lower state has only one possible interpretation, with a calculated absorptive width of about 7 MeV, consisting of the Σ-hyperon attached to the low-lying spinless isospin-0 states of ^8Be. The outstanding candidate for the upper peak is the isospin-2 configuration built on the isospin-1 ^3P core occurring at about 17 MeV in ^8Be, for which the calculations give $\Gamma = 6$ MeV, but there are a number of other $A=9$ Σ-hypernuclear states with predicted widths of less than 12 MeV.

When these interpretations have been tested in more detail and verified, the properties of these exceptional states will give us information about the ΣN interactions otherwise difficult to obtain. First, their absolute location will determine the mean Σ well depth U. The spacing between the two ^9Be peaks will give another measure of this real part of the ΣN potential. The most interesting situation will be that for target ^{16}O, which contains both $p_{3/2}$ and $p_{1/2}$ nucleons. Two particle-hole states exist, which can both be produced coherently; their wave-functions are linear superpositions of the two configurations $((1p_j)_N^{-1}(1p_j)_\Sigma)_{J=0}+$, for $j=3/2$ and 1/2. The measurement of their spacing will give us a measure of the ΣN spin-orbit interaction, just as we have recently learned the strength of the ΛN spin-orbit interaction from the spacing between the corresponding $^{16}_\Lambda O^*$ states (Brückner et al., *Phys. Lett,* **79B**, 157; 1978). With data having less background, it may be possible to see the Σ-hypernuclear spectrum in more detail and to learn empirically about the spin-spin and isospin-isospin components of the hyperon-nucleon forces. An improved K^- beam is now being installed at CERN to allow these Σ-hypernuclear experiments to be carried out for lower incident momenta $p_{\bar{K}}$, closer to the magic momentum $p_0(\Sigma) \simeq 280$ MeV/c, so that the coherent states with narrow width will stand out more strongly in the data. We may expect more information on the Σ-nucleus interaction from this experimental program during 1981. □
The Pribram fireball. A rotating shutter cut off the light ten times a second. The number of breaks in the trail shows the meteor took seven seconds to cross the photograph. (Ondrejov Observatory, Czechoslovakia)

The problem becomes much more difficult in the case of the large meteorites. These lose the majority of their mass in the lower atmosphere where the mean free path of the air molecules is very much smaller than the size of the incoming object. So a large aircap is formed around the meteorite, shock waves occur in the region between this aircap and the atmosphere it is moving into and the meteorite is followed by an active, turbulent wake. Visual radiation is usually emitted from all these regions as well as from the meteorite itself. There is also another complication. Observations of meteors using Super Schmidt cameras have shown that the small meteoroids do not decelerate appreciably in the atmosphere. The loss of energy they suffer is exhibited by a mass loss rather than a velocity loss. The observed radiation also comes in the main from the ablated meteoroid atoms. The large meteorites however do decelerate. In many cases they are retarded to the free fall velocity and the remnants of the meteorite drops to the Earth's surface. Radiation also comes from many sources.

The luminous efficiency of meteoritic fireballs has been discussed in detail in a recent paper (*J. geophys. Res.* **84**, 6255; 1979) by Douglas ReVelle of Northern Arizona University and R. S. Rajan of the Carnegie Institution of Washington.

The authors stress the fact that the majority of the radiation from the fireball, when it is low down in the atmosphere, is in the ultraviolet region of the spectrum. They also take into account the deceleration term for the first time. Their theoretical work can unfortunately only be checked by reference to three meteorite entries. The first is the Pribram meteorite which fell in Czechoslovakia in 1959. The fall was photographed by a series of all sky camera's and the authors estimate that about 53 kg of meteorite eventually hit the earth even though outside the atmosphere the meteorite had a mass of around 1300 kg. — a loss of 96% of the mass. The other two meteorites, Lost City and Innisfree fell and were photographed in North America. In both cases about 70% of the initial mass was lost as the object came through the atmosphere. These mass loss figures are supported by an analysis of the cosmic ray tracks in the recovered meteorites. The

Meteoritic fireballs and luminous efficiency

from David W. Hughes

LUMINOUS streaks of light flashing across the sky are caused by cosmic dust particles burning out in our atmosphere. They are a common enough phenomena and have been seen ever since man looked up to the heavens, but even to-day they still present problems. One of the more pressing ones is the discovery of the exact relationship between the light intensity of the trail and the mass and velocity of the incident object. Things are relatively simple if the incident particle is less than about 1 cm in radius. These small meteoroids burn out at heights between about 80 and 110 km, in an atmospheric region where the mean free paths of the molecules are much larger than the meteoroid dimensions. The atoms that ablate from the particle leave without serious mutual interference. They have

David W. Hughes is in the Department of Physics, University of Sheffield.

kinetic energies of a few tens to some hundreds of electron volts and are thus excited and ionized. Also they can excite and ionize the molecules they collide with. Excited atoms and molecules emit radiation and the luminous power so produced has been found to be proportional to the rate of loss of kinetic energy of the ablated atoms. The constant of proportionality, known as the luminous efficiency factor, depends on the velocity of the incident meteorite, its composition (stone, iron, stoney iron) and its physical structure (i.e. whether it is a solid body or a dust ball).

Most of the early work in this field was done by Öpik and he prepared an indispensable series of tables which enabled the initial masses of small meteoroids to be estimated from measurements of the meteor luminosity and the meteoroid velocity.

bombardment of the meteorite in space by cosmic rays produces a network of radiation damaged material. The density of this network shows appreciable depth dependence and a measurement of this density in the recovered meteorite leads to an estimate of how much material overlayed that region when it was in space.

The photographic records of these meteorites are of paramount importance because from them the velocity of the meteorite and the luminosity of the fireballs may be calculated as a function of height. ReVelle and Rajan applied their theoretical model to the observed light and velocity profiles and, after introducing a few assumptions (such as that the radiation field was isotropic and that the mass of the main body at any specific moment is much larger than the mass of the associated fragments), they obtained a curve which showed how the luminous efficiency varies as a function of height in the atmosphere and as a function of meteorite velocity.

The authors compared their results with a low velocity laboratory simulation experiment carried out by Givens and Page (*J. geophys. Res.* **76**, 1039; 1971). Here artificial meteors were produced by firing 0.6 mm stainless steel spheres with a light gas gun into a column of still air at 0.052 atmospheres of pressure. The resulting 'meteor' train was observed using a series of broad band multiplier phototube radiometers. The velocities of the spheres were about 8 km s^{-1} in comparison to the Pribram meteorite which initially had a velocity of 21 km s^{-1} and Lost City and Innisfree meteorites which had velocities about 14 km s^{-1}. When corrections were made for the velocity effect the results agreed very well.

The main conclusion of ReVelle and Rajan is that there is a phase lag between the ablation of meteoritic material and the emission of luminosity. The luminous efficiency was found to be a rather complicated function of the meteorite velocity. Also when the meteorites Lost City and Innisfree were losing mass at the maximum rate, the luminous efficiency in the visible wavelength region of the spectrum was about 0.3%. For the faster Pribram meteorite the value was about 0.04%. The authors adding the proviso that the Pribram results are regarded as being less reliable.

It is important to note that the 0.3% result is a factor of between 5 and 10 higher than the empirical luminous efficiency assumed by Ceplecha and McCrosky (*J. geophys. Res.* **81**, 6257; 1976) in their analysis of fireball trails. This means that even though only 3 parts in 1000 of the energy lost by a meteorite goes into visual radiation this is considerably more than was estimated previously. So, bright fireballs are now thought to be produced by smaller incident meteoroids and the total mass of cosmic material hitting the Earth in the fireball size range has to be revised downwards by a factor of 5 to 10. □

METEOR SHOWERS
Shower of Aquariads July 27–30th.

SEVERAL of the meteor streams observed at Bristol within the last two years appear to be of such marked intensity as to merit special description, and the following notes in connection with them may possess some interest to observers.

My observations in July, 1878, led me to recognise a large number of slow meteors with long paths (averaging 17°) and occasionally leaving faint trails of sparks, ascending amongst the stars of Pegasus, Andromeda, &c., which, by their parallelism of motion, obviously proceeded from a common radiant point south of Pegasus. I watched them narrowly, and determined the position with fair precision as near δ Aquarii.

A succession of clear nights occurred from July 26 to August 2 in 1878, and I obtained some lengthy observations. In about twenty-two hours of watching more than 400 shooting stars were seen in the eastern sky, chiefly amongst the constellations of Perseus, Cassiopeia, and Andromeda. I saw many swift meteors leaving short streaks and otherwise exhibiting much uniformity in their appearances and directions. The radiant point was not reconcilable with that of the well-known annual shower of Perseïds. It was sharply defined about 3°S. of the group χ Persei, and the maximum of the shower was witnessed on July 31, when 21 meteors were noted diverging from the point described.

Shower of Perseids II July 28–August 1st.

From *Nature* **21**, 29 April, 621; 1880.

The Uninvited Guests

from Graham Darby

MOST people are no doubt unaware that they are accompanied through life by several herpes viruses lying dormant in the tissues of their bodies. The human herpes viruses have the characteristic of establishing long-term relationships with their hosts, emerging only infrequently to cause disease.

Since these viruses are ubiquitous in the population the first encounter between the infectious agent and its human host usually occurs early in life and results in an in-apparent infection or rather mild disease. In the developed countries of the world this initial encounter often occurs later in life and, paradoxically, this delay may result in a more serious primary disease. Subsequently the viruses remain with us for life. There is little evidence that cytomegalovirus (CMV) or Epstein-Barr virus (EBV) usually cause further problems but both herpes simplex (HSV) and varicella-zoster (VSV) which establish latent infections in the peripheral nervous system may re-emerge to cause recurrent episodes of disease. HSV type 1 causes periodic eruptions of cold sores around the mouth but these generally heal quickly and leave no scars. However, a closely related virus, HSV type 2, is more damaging as it usually infects the genital regions where it causes a painful and often socially embarrassing disease. Indeed, in some areas of the world it is emerging as the most common problem seen in V.D. clinics. VZV can remain latent for many years after childhood chicken pox but it too many reactivate, usually late in life, to cause shingles.

An overall view of our understanding of these agents and the diseases caused by them was provided by a meeting in Atlanta this Spring*. Both virologists and clinicians attended the meeting and the growing clinical importance of molecular biology was nicely demonstrated by B. Roizman

Deep sea diving

from M. J. Halsey

A new record was recently set at Duke University when three men successfully underwent conditions simulating a dive to a depth of 650m of sea water. This achievement set the background for a recent workshop* on the problems of very deep dives, in the range 460-760m (1500-2500ft).

Fifty years ago men dived using only compressed air but nitrogen narcosis, which increases with increasing partial pressure of the gas, effectively prevented this technique from being used at depth. The subsequent development of helium/oxygen mixtures allowed safe diving to depths beyond 50m, but problems develop when the 450-550m range is reached. At these depths the high pressure neurological syndrome (HPNS), characterised by muscular tremor, disorientation, and short sleep-like periods of loss of attention develops; in animal experiments even higher pressures have been shown to cause convulsions. However, a breakthrough has now been achieved by the discovery that HPNS can be overcome by the use of low partial pressures of anaesthetics. It is this that has lead to new techniques and to new records in deep diving. In experiments with animals, gases with anaesthetic action such as nitrogen or nitrous oxide and low doses of intravenous anaesthetics such as ketamine or althesin have been found effective. Nitrogen deliberately introduced in small quantities into the helium/oxygen breathing mixture was the basis of the trimix which was used in the record chamber dive. This has also been used in the successful open sea dive to 460 m by Comex, S.A. Marseille, which has set a new standard for deep

water work.

Current work on a wider pharmacological approach to the problem suggests that selective drugs for HPNS may exist. Structural isomers of some steroid anaesthetics, such as althesin, have been found in animals to continue their action against HPNS even though they no longer have anaesthetic effect.

Additional problems in deep diving include those of temperature control, respiration and decompression. Temperature control is of great concern in working dives because high pressure seems to affect the body's thermoregulatory capacity. Not only is there a narrowing of the limits within which the body can make corrections to mantain a stable temperature but also the subjective experience of heat and cold may become divorced from actual conditions.

Respiration in chamber dives is not a general problem but dyspnoea, exacerbated by exercise, is present. This could become a limitation in future deep dives. The phenomenon appears to be unrelated to gas density but is an aspect of HPNS that is not alleviated by nitrogen. Decompression from deep depths is proving possible although recompression or a change of gas breathing mixture may prove difficult.

Although diving beyond 460 m has now certainly been made possible, and both naval and commercial interests agree there will be a definite need for such dives, it must be remembered that the principles underlying the effects described above are not at all understood. The number of men who have been beyond 300m remains very small; only an understanding of the basic mechanisms involved can ensure that such deep dives can continue in safety.   □

---

extremely strong, but much less certain is the connection between HSV type 2 and cervical cancer. R.P. Eglin and his colleagues (Institute of Virology, Glasgow) reported some very careful *in situ* hybridization experiments which showed low level expression of HSV-specific RNA sequences in pre-invasive and invasive carcinoma tissues, while two groups reported the induction of cervical carcinomas in animal model systems, W.B. Wentz and colleagues (Case Western Reserve University, Cleveland) using inactivated HSV type 2, and C. Minhui and associates (Hupei Medical College, Wuhan, China) using live virus. A very large prospective study to determine the risks associated with HSV type 2 infections in women is currently underway in Czechoslovakia (V. Vonka and colleagues, Institute of Sera and Vaccines, Prague) involving colposcopy, cytological smears and blood tests on 10,000 women selected at random.

One of the tantalizing questions about herpes viruses is how latent infections are maintained for long periods. What factors are important in the suppression of the infection? This is an area in which very little real progress has been made although it is generally accepted that specific antibodies are important in maintaining HSV latency. However some elegant experiments described by H. Openshaw (University of California, Sacramento) using a mouse model throw considerable doubt on this idea. Latent infections were established in mice which were protected during the primary infection by administration of immune antibody so that their own immune systems were not primed. It was shown in the majority of animals that as the passive antibodies faded the latent infections were maintained.

From the clinical point of view there are two areas which require urgent attention. The clinician would like to be in a position to offer some protection to a patient (e.g. a prospective organ recipient) who he knows will be at risk from these viruses in the immediate future. Such protection could be generated by a suitable vaccine. Secondly he needs effective drugs to control the more serious diseases associated with these viruses. There appear to be encouraging developments in both areas.

The problems associated with assessing the safety of attenuated herpesvirus vaccines are considerable since we have to take into account not only the primary infection but also recurrent disease and the oncogenic potential of these viruses. Attenuated VZV vaccine strains have been developed and are in use in some countries although the prevailing view, expressed by P.A. Brunnel (University of Texas), was that these vaccines should be used only in cases where patients are exposed to serious risk. An attenuated CMV vaccine has also

---

(University of Chicago). Over a brief period there were 8 cases of HSV encephalitis at Massachusetts General Hospital, and since this is an extremely rare disease it was inevitably thought that the epidemic was caused by a particularly neurovirulent strain of virus. However, restriction enzyme analyses were made on the genome DNA of viruses isolated from all 8 patients and as the patterns were distinct from each other it was proven that the cases were caused by different virus strains.

The viruses may be particularly dangerous in two situations; infections of the newborn and of the immunosuppressed. CMV may cross the placenta and infect the fetus sometimes causing severe brain damage. HSV may be contracted from the infected genital tract of the

mother leaving the fetus with only a 50/50 chance of survival (A.J. Nahmias, Emory University, Atlanta). HSV, CMV and VZV are all common infections of immunosuppressed patients such as those under-going cancer therapy or organ transplantation. The diseases in these patients are often very severe and they are a significant cause of death. There were also suggestions that such diverse conditions as hardening of the arteries and psychotic depression (S. Sprecher, Institut Pasteur du Brabant) and even gastric ulcers (B.F. Vestergaard, Institute of Medical Microbiology, Copenhagen) might be initiated by recurrent HSV infections.

It has long been debated whether herpes viruses are involved in the induction of human cancers. Certainly the association between EBV and Burkitt's Lymphoma is

Graham Darby is in the Department of Pathology, University of Cambridge.

been developed and is undergoing clinical trials for renal transplant patients (S.C. Marker and H.H. Balfour, Jr., University of Minnesota). In the case of HSV and EBV where the oncogenic potentials are more clearly defined the development of attenuated strains has apparently been ruled out. Attention with HSV has been focused on nucleic acid-free subunit vaccines. The use of monoclonal antibodies in animal model systems has the potential to tell us which antigens are likely to elicit a protective response (R. Dix and colleagues, Veterans Administration Medical Center, San Francisco). These vaccines may also have problems associated with them since they are unlikely to generate long term immunity and there may be dangers in delaying primary infection.

Chemotherapy of herpes virus infections has been hampered by the toxicity of the antiviral compounds available, so that treatment has been limited to topical application or desperate situations. However excitement is now running high as we appear to be entering a new era with the appearance of several low toxicity nucleoside analogues which are extremely effective against HSV. The most exciting of these compounds, Acyclovir, has generated very encouraging results in animals and the results of trials in humans are eagerly awaited.   □

Free-electron lasers

from J.N. Elgin

IN conventional laser systems, gain is obtained as a consequence of electronic transitions between bound states of the host substance. As a result, the gain band width of the laser is limited by the line width of the relevant bound-bound transition. In free-electron laser systems the electrons are free and gain is produced by the interaction of these free electrons, with the static magnetic field, as discussed below. Thus, these systems have the attractive advantage that their gain band width is, at least in principle, infinite.

Much interest has been generated in free-electron lasers since the recent experiments of Madey and coworkers at Stanford (*Phys. Rev. Lett.* **38**, 717; 1976; ibid **38**, 892; 1977). In their first experiment, the system was operated as a single pass amplifier and gain was demonstrated at 10.6μ, and in their second the system operated as a laser oscillator with output at 3.4μ.

For each case, the basic experimental arrangement can be represented schematically by the full outline in the figure. Here, a relativistic electron beam traverses a periodic magnetic structure and, in so doing, emits synchrotron radiation into the forward direction. Stimulated emission of this radiation can occur in the vicinity of the resonance frequency (J.D. Lawson, *Nature* **277**, 262; 1979)

$$\omega_r = ck_T = \frac{c\beta}{1-\beta k_o}$$

where $c\beta$ is the component of the electron velocity along the symmetry axis, and $k_o = 2\pi/\lambda_o$ is the wave number of the static "wiggler" field. The gain curve for stimulated emission is markedly different from that encountered in conventional laser systems, being asymmetric about the resonance frequency ω_r (resembling somewhat an anomalous dispersion curve with resonance at ω_r). Only frequencies to one side of resonance are amplified, while those in the complementary region are strongly absorbed.

In each of the above experiments, electrons were passed only once through the apparatus, then discarded. In the experiment demonstrating gain at 10.6μ, it was found that about 0.2% of the electron's energy was converted to radiation without any evidence of saturation. It would appear at first sight that this efficiency could be vastly improved simply by recirculating the electrons in a storage ring in which an r.f. cavity makes good all energy losses to radiation (i.e. in both the laser cavity and the ring), as indicated by the remaining part of the figure. In this way, efficiencies of, say, 20% or greater may be possible.

Unfortunately, energy spread of the input electron beam during transit through the laser cavity raises a nontrivial objection to the above scheme. Normally, the electrons enter the laser cavity with random optical phase so that $v_1\varepsilon$ — where v_1 is the transverse component of the electrons velocity and ε is the electric field strength of the laser radiation — is just as likely to be positive as it is negative. In other words, just as many electrons are extracting energy from the radiation field as are contributing energy to the field. The energy spectrum of the electrons therefore broadens (laser heating) and this effect is in general much larger than the (second-order) shift of the energy mean, which determines the net energy loss to the radiation field. Unless the recycling scheme can counteract this spread, it will become progressively larger with each transit, with a corresponding decrease in gain, until eventually the laser system ceases to function.

The simplest way in which the storage ring might be used to eliminate spread is quite simply to use radiation losses in the ring to damp out the spread. The radiative energy loss by a particle moving round the ring increases with increasing values of energy of the particle, and so a broad energy distribution necessarily narrows. The r.f. cavity makes good all radiative losses and the cycle is repeated, converging ultimately to the point where the spread has a constant value at input to the laser cavity. Of course, if this steady state distribution is too broad, the gain may become negligibly small and the laser will cease to function.

A more detailed study of the combined storage-ring laser system has recently been published by Deacon and Madey (*Phys. Rev. Lett.* **44**, 449; 1980). The object here is to determine whether there are any possible conditions under which the electrons have isochronous orbits for transits through the complete system; that is, where the period for the complete orbit (laser plus storage ring) is independent of the initial conditions of the electron. Such a system necessarily has the required property of reversing the spread. The assumption is first made that the laser is operating in the Compton (or single particle) regime — which is the case for the experiments at Stanford — and the motion of the electrons through the laser cavity is accordingly modelled by the pendulum equation (Colson, *Phys. Lett.* **64A**, 190; 1977)

$$\frac{\delta^2\theta}{\delta t^2} = -\Omega^2 \sin\theta$$

Here, $\theta = k_r\delta Z(t)$, where k_r is the wave number for the radiation field inside the

Storage Ring

R.F. Generator
IN a recent paper in Astrophysical Journal (**235**, 625; 1980) H. Yoshimura has presented new results from computational simulations of non-linear astrophysical dynamos; in particular he has reproduced magnetic Field reversals. This represents a contribution to the theory of field generation (i.e. dynamo action) in a sphere of electrically conducting fluid, the object of such investigations being to explain the observed features of the magnetic fields of the Earth and the Sun. In the terrestrial context, it is necessary to explain why the magnetic field of the Earth survives in a quasi-steady state over geological time scales much longer than the natural decay time of the field (of order 10^4 years). In the solar context, it is necessary to explain why the general magnetic field of the Sun evolves in an approximately periodic manner (with the same period as that of the sunspot cycle i.e. about 22 years) when the natural (ohmic) time scale for the Sun is of the order of 10^9 years.

Traditional dynamo theory starts from coupled equations for the velocity field **u** and the magnetic field **B** in the fluid region

$$\left. \begin{array}{c} \dfrac{\delta \mathbf{B}}{\delta t} - \lambda \nabla^2 \mathbf{B} = L\{\mathbf{u}, \mathbf{B}\} \\[2ex] \dfrac{\delta \mathbf{u}}{\delta t} - \nu \nabla^2 \mathbf{u} = N\{\mathbf{u}, \mathbf{B}\} + \mathbf{F} \end{array} \right\} \quad (1)$$

In these equations L represents a differential operator that is linear in each of **u** and **B**, N represents a nonlinear integral-differential operator, and **F** represents the force distribution, whatever this may be, which maintains the motion. Much controversy surrounds the nature of this force field in the terrestrial context, but in the solar

H.K. Moffat is in the School of Mathematics, University of Bristol.

Non-linear astrophysical dynamos

from H.K. Moffat

context it is certainly of thermal origin.

For a given force field, one would like to solve these equations, and demonstrate the existence of solutions for **B** which have the observed property in either context. Unfortunately, this task is far beyond either analytical solution, or the power of present computers. Approximate techniques must be adopted in order to reduce the problem to a level that will yield to the computer. A first dramatic stage has been achieved over the last 20 years, with the realisation that when the velocity field **u** is turbulent, the mean magnetic field <**B**> satisfies a simpler equation

$$\left(\frac{\delta}{\delta t} - \lambda \nabla^2 \right) <\mathbf{B}> = <L><\mathbf{B}> \quad (2)$$

where <L> is an averaged differential operator which is in principle determinate in terms of the statistical properties of the turbulence. For different forms of this averaged operator, solutions of equation (2) are known of types that capture the main features either of the Earth's quasi-steady field, or of the Sun's quasi-periodic field.

The magnetic field itself influences the structure of the turbulence, through the second of Equations (1), and it is this "back reaction" effect that more recent theories are attempting to incorporate. First attempts in this direction were those of Stix (*Astron. Astrophys.* **20**, 9; 1972) and Jepps (*J. Fluid Mech.* **67**, 417; 1975), both of whom incorporated a fairly simple cut-off in the "regenerative" part of <L> when the magnetic field exceeded

a level at which the back reaction effect was assumed to become significant. Yoshimura has developed this approach in a series of papers, in which he has considered increasingly sophisticated forms of the operator <L>, incorporating in particular a time-lag between the generation of a magnetic field and the (later) manifestation of its dynamic effects. This increasing sophistication in his models has enabled him to compute solutions of Equation (2) which resemble the observed fields of Earth and Sun in remarkable detail. As might perhaps be anticipated the more disposable parameters that are introduced in the assumed form of <L>, the more freedom there is at the end of the calculation to choose these parameters in a way that achieves agreement with observation. In particular, Yoshimura has now found solutions exhibiting reversals, like the well-documented occasional reversal of the Earth's field.

While Yoshimura's approach does not increase physical insight at the fundamental level, it does lead to the accumulation of an interesting catalogue of possible behaviours of solutions of equations of the form (2), when time delay is incorporated in the operator <L>. The approach however is open to criticism in that all the subtleties of the dynamical equation (1b) are parametrized in what many would regard as an unacceptably crude manner. Alternative approaches (e.g. that advocated by Malkus & Proctor (*J. Fluid Mech.* **67**, 417; 1975) treat the dynamics in a less brutal manner, and although such approaches have not yet been pushed as far (in terms of results) as Yoshimura's, they hold more promise in the longer term for providing a convincing theory of dynamo action including proper recognition of the role of dynamic effects. □

---

cavity and δZ is the longitudinal deviation from resonance, and $\Omega^2 \alpha B_0 \varepsilon$, the product of the wiggler field strength and the electric field amplitude of the generated radiation. The physics of electron bunches moving round storage rings is in general very complicated. However, as a first approximation, the ring system can also be modelled by a pendulum equation of the above type, where θ is now proportional to τ, the time displacement of a test particle from the nominal position, and $\Omega^2 \alpha V$, the amplitude of the applied r.f. field.

For either system (laser or ring) taken in isolation, the above equation predicts trapped particle solutions, where the particles oscillate backwards and forwards in the potential wells determined by Ω — a phenomenon well known in plasma physics. The length scale of the potential wells (or 'buckets') will of course be different in the two systems, being very much shorter in the laser cavity where they

are of the order of the optical wavelength. If the two systems are now coupled, as shown in the figure, we have a very complicated system indeed comprising as it does two coupled highly nonlinear differential equations. Clearly, such a system can only be properly studied using numerical techniques.

In their preliminary study of the problem, Deacon and Madey proceed by linearising the above system and, in so doing, are able to establish that isochronous orbits *will* occur provided the operating parameters of the system fall within defined limits. Within these limits, the large operating efficiencies (> 20%) referred to earlier should be realised. It will be interesting to see whether a more complete (numerical) study of the problem confirms these preliminary results.

J.N. Elgin is in the Department of Physics, Imperial College, London.

It is perhaps worth while mentioning two alternative schemes to the laser-ring system discussed above, both of which have received some theoretical study. In the first of these, an attempt is again made to reverse the energy spread of the electrons, but this time using echo techniques. Here, the effect is similar to one obtained in nonlinear optics where a randomising process can be reversed by a suitable coherent interaction of an optical pulse with the system. The second alternative uses a tapered wiggler magnet to slow down the electron bunches trapped in the optical potential wells referred to earlier, with the loss in energy of the bunches going into the radiation field. This latter method would of course be single pass only. Each possible method has its advantages and disadvantages and, at the time of writing, it is not yet clear which (if any) will provide the means of obtaining high efficiencies in free-electron laser systems. □

REVIEW ARTICLE

Biosynthesis of the pigments of life: formation of the macrocycle

Alan R. Battersby, Christopher J. R. Fookes, George W. J. Matcham & Edward McDonald

University Chemical Laboratory, Lensfield Road, Cambridge CB2 1EW, UK

The organic nuclei of chlorophylls, haems, cytochromes and vitamin B_{12} are biosynthesised from a single tetrapyrrolic intermediate which has an unexpected, rearranged structure. The mechanism of biosynthesis of this key intermediate has now been characterised in detail. Some of the information thereby obtained is also of use in the investigation of human diseases such as the porphyrias.

MANY vitally important functions in living systems are carried out by metal ions held as complexes within tetrapyrrolic macrocycles. Photosynthesis depends on chlorophylls (Mg^{2+} complexes), whilst the oxygen-carrying properties of haemoglobin and myoglobin are based on the Fe^{2+} complex (protohaem) of the macrocycle protoporphyrin-IX (compound 6). Electron transport, reduction of oxygen and hydroxylation reactions are mediated by a family of cytochromes which similarly depend on Fe^{2+} complexes (haems). Also, vitamin B_{12} is a related complex of Co^{3+}. Thus the entire group of macrocyclic pigments can fairly be called the pigments of life. This review outlines the highlights from 10 years of work aimed at discovering the biosynthetic pathways by which the organic macrocycles of these pigments are built. Only by having a full understanding of the normal biosynthetic processes can one pinpoint the failures which lead to disease.

Living systems tend to synthesise many complex molecules by assembling and/or modifying a relatively small number of starting materials[1]. This is certainly true for the macrocyclic pigments. Indeed, all the natural pigments mentioned above are biosynthetically derived from a single intermediate, uroporphyrinogen-III (3) (uro'gen-III). In plants, animals and most bacteria, the major forward pathway then involves decarboxylation of uro'gen-III (3) to yield coproporphyrinogen-III (copro'gen-III) (4), which by oxidative decarboxylation produces protoporphyrinogen-IX (proto'gen-IX) (5). Aromatisation of proto'gen-IX (5) gives protoporphyrin-IX (6) from which one set of pigments is built, as shown in Fig. 1. A second branch from uro'gen-III (3) leads via cobyrinic acid (7) to vitamin B_{12}; here, the key modifying process is not oxidation but methylation on carbon.

This central position for uro'gen-III (3) in a family of pigments of immense biological importance, emphasises the value of understanding its biosynthesis.

Building blocks and enzymes

Shemin, Granick, Bogorad, Neuberger and Rimmington had shown in pioneering work[2] that two enzymes are required to catalyse the conversion of four molecules of the monopyrrole porphobilinogen (PBG) (1) into uro'gen-III (3) and ammonia (Fig. 1). The names of these enzymes 'PBG-deaminase' and 'uro'gen-III cosynthetase' will be shortened here to deaminase and cosynthetase. In the absence of cosynthetase, deaminase catalyses the conversion of PBG into uro'gen-I (2), an unnatural isomer but the one expected from simple head-to-tail combina-

tion of four PBG units. However, uro'gen-I (2) is not converted into uro'gen-III (3) by cosynthetase nor by the complete deaminase–cosynthetase system. It is fascinating that living systems have developed during evolution a highly specific method of catalysing a rearrangement process which produces the unexpected type-III isomer (3), having adjacent propionate groups on rings C and D. How do the two enzymes work together to achieve the synthesis and what are the intermediates? These problems have a special fascination because four identical building blocks (PBG) are used for uro'gen-III (3); because they are identical new approaches had to be devised to solve this riddle.

Nature of the rearrangement

To produce uro'gen-III (3) from PBG (1), deaminase–cosynthetase must be capable at some stage of breaking the bond linking the C-11 methylene group to its pyrrole nucleus for one or more of the four PBG units. Obviously, there are many ways in which four pyrrole rings and the four methylene groups can be shuffled to produce uro'gen-III (3). It is a measure of the intense interest in this problem that at least 25 hypothetical schemes have been proposed for the biosynthetic process.

The various possible ways of building uro'gen-III (3) from PBG (1) differ in which of the four bridge carbons (C-5, 10, 15 and 20) are still attached to the same carbons at the same pyrrole nuclei as they were in the original PBG units. Methods had therefore to be found to study processes which break established C—C bonds and make new ones. ^{13}C-NMR proved to be a suitable method. The principle of this approach is simple; the ^{13}C-NMR signal from a ^{13}C-atom is affected by another ^{13}C-atom only if both are in the same molecule. Parallel synthetic work showed[3,4] that two directly bonded ^{13}C-atoms (●—●, Fig. 1, structure (6)) give characteristic ^{13}C-NMR signals, easily distinguishable from those given by ^{13}C-atoms separated by three bonds (for example, ▲—C—N—▲, structure (6)). These in turn were clearly different from the signals given by two ^{13}C-atoms in different molecules.

PBG (1a, Fig. 2) was synthesised carrying 90 atom% ^{13}C at both C-2 and C-11; thus 81% of the PBG molecules carried two ^{13}C-atoms. This product (one part) was diluted with unenriched PBG (four parts) in which a negligible proportion of molecules carry two ^{13}C-atoms at C-2 and C-11. Incubation of the resultant PBG sample with an enzyme system rich in deaminase–cosynthetase from *Euglena gracilis* first produced uro'gen-III (3a). However, because the biological system contained all the
Fig. 1

enzymes necessary to convert uro'gen-III, as it was formed, into protoporphyrin-IX (6) by the steps shown in Fig. 1, it was this porphyrin which was isolated.

^{13}C-NMR then proved[5,6] that the ^{13}C-pattern of the labelled protoporphyrin-IX was as shown in structure (6). The geometrical shapes each represent a ^{13}C-atom and those given the same shape were proved to be present in the same molecule. As protoporphyrin-IX is formed from uro'gen-III without disruption of the macrocycle (Fig. 1) the results for the former also hold good for the latter (3a, Fig. 2). Exactly the same pattern was found[5,6] when the experiment was repeated: (i) with an enzyme preparation from chicken's blood; and (ii) using *Propionibacterium shermanii*. It follows that the deaminase–cosynthetase system assembles four PBG molecules to form uro'gen-III in exactly the same manner in a photosynthetic alga, in avian blood and in a bacterium, and the mode of assembly, not considering the mechanism at this stage, is that illustrated in Fig. 2.

Timing of the rearrangement step

Thus three PBG units are built intact into uro'gen-III (3) together with one intramolecularly rearranged unit corresponding to ring D and C-15. In principle, the single rearrangement could occur at any stage in the overall process, at the monopyrrole, dipyrrole, tripyrrole or tetrapyrrole levels. In fact, many experiments with mono- and dipyrroles pointed strongly to rearrangement at the tetrapyrrole level[7-9], in contrast to other claims[10-12].

Proof that this is the case came from synthesis of the bilane (Fig. 3, 9a) corresponding to straightforward, head-to-tail joining of four PBG units. It was first made in unlabelled form[13] but later carrying two ^{13}C-atoms[14]. One sample was labelled with 90 atom% ^{13}C at ● (9b) and the other at ▲ (9c) and both were diluted with unlabelled material before use (compare with the earlier work with PBG[14]).

To determine what happens non-enzymatically to the bilane samples (9b and 9c), they were allowed to ring-close at pH 7, and the product in each case was shown to be almost pure uro'gen-I (2b and 2c), with only traces of other isomers[13,14]. Thus no significant chemical rearrangement occurred and the foundation was established for the key enzymatic experiments. These involved separate incubation of each of these diluted samples (9b and 9c) with deaminase-cosynthetase. Strikingly, the product in each case now contained 80% uro'gen-III (3b and 3c) and only 20% of uro'gen-I (2b and 2c). The same bilane in the unlabelled form was prepared by a different method[15] and deaminase-cosynthetase from *P. shermanii* partly transformed it into uro'gen-III (type-III: type-I ratio 16:84). ^{13}C-NMR of the type-III isomer isolated from one experiment showed that the two ^{13}C-atoms, shown as ● in Fig. 3, 3b, had become bonded intramolecularly. The same was true in the other experiment for the two ^{13}C-atoms marked ▲ (Fig. 3, 3c). The ^{13}C-spectra were run on the derived coproporphyrin-III tetramethyl ester (10b and 10c), obtained by aromatisation of uro'gen-III with iodine, decarboxylation of the acetic acid side chains and esterification. The ▲ labels in the second experiment above lie at the two ends of the bilane (9b) so the further important conclusion could be drawn that the entire bilane (9c) was converted intact into uro'gen-III (3c).

The above studies depended on quantitative determinations of the amounts of uro'gen-III (3) and uro-gen-I (2) (and also the type-II and type-IV isomers) present in a mixture of these macrocycles. In carefully selected conditions, separation of the four coproporphyrin methyl esters derived from the uro'gens was achieved in a single HPLC run, a method which could be adapted to the analysis of porphyrin isomers from porphyric patients.

It is now firmly established that the deaminase–cosynthetase system brings about head-to-tail assembly of four PBG units to form an unrearranged bilane (8). A group X is shown in Fig. 3 because it was clear that the $^+$NH$_3$-group of PBG (1) (and similarly the $^+$NH$_3$-group of the $^+$NH$_3$CH$_2$-bilane (9a)) might be enzymatically replaced before the final ring-closure with rearrangement[14,16]. It was envisaged that the group X could be some nucleophilic group on the enzyme or an external nucleophile. The unrearranged bilane (8) is then enzymatically transformed intact into uro'gen-III (3) with intramolecular inversion solely of ring D, exactly as found earlier for PBG (1). Rings A, B, C and D of the bilane (8) correspond respectively to rings A, B, C and D of uro'gen-III.

Order of assembly of the four pyrrole rings

Is there an obligatory order of assembly of the bilane (8)? If so, does the first PBG unit enzymatically bound eventually become ring A of bilane (8), and so ring A of uro'gen-III, followed by sequential addition of ring B, ring C and finally ring D, or vice versa?

Answers came only after isolation of a relatively large quantity of enzyme. Approximately 0.25 μmol of deaminase-cosyn-
Fig. 2

thetase was treated with a deficiency (~0.5 μmol) of unlabelled PBG (1). This was designed to produce the greatest 'loading' on to the enzymatic site to which the first PBG binds. The corresponding 'loadings' at the other sites should decrease in a stepwise way so that the last site to be filled should carry least. The loading referred to covers pyrrolic material on that site whether it be monopyrrole (for example Fig. 4, 12) or part of a di- (for example, 13), tri- (14) or tetrapyrrole (8). An excess of 90 atom% [11-^{13}C]PBG (Fig. 2, 1b) was then added to chase through the bound pyrrolic species to form uro'gen-III (3) which as earlier was converted into coproporphyrin-III methyl ester (11) for NMR study.
Fig. 3

The ^{1}H-NMR signal from a ^{1}H-atom attached to, for example, C-20 of compound (11) will give a singlet if C-20 is a ^{12}C-atom but a widely split doublet will appear if C-20 is a ^{13}C-atom. Thus the size of the central ^{1}H-singlet is a measure of the ^{12}C content at that 'bridge' position. It can now be seen clearly from Fig. 5 that the ^{12}C-content is greatest at C-20 and that the ^{12}C-levels at the other bridge carbons fall in the order C-5 > C-10 > C-15. Thus[17] the first PBG unit to bind becomes ring A (with C-20), the second ring B (with C-5), the third ring C (with C-10) and the last ring D (and C-15). The same conclusion is reached independently in a recent study based on ^{14}C-labelling[18].

The intermediate hydroxymethylbilane

The studies so far made use of the complete deaminase–cosynthetase system but further progress demanded the individual enzymes; they had not been separated previously from *Euglena gracilis*. Classical work[19,20] showed that cosynthetase from other sources is thermally less stable than deaminase, and this holds true for the *Euglena* enzymes. However, both enzymes from *Euglena* are sufficiently stable to be cleanly separated chroma-

tographically and handled with workable levels of activity (ref. 21 and G.W.J.M., E.McD. and A.R.B., in preparation).

When deaminase–cosynthetase acted on the $^+$NH$_3$CH$_2$-bilane (9a), as outlined above, there was enzymatic acceleration of the ring-closure, relative to the non-enzymatic rate, and the formation of uro'gen-III (3) showed no lag phase. However, when the $^+$NH$_3$CH$_2$-bilane (9a) was incubated with deaminase (free of cosynthetase), there was an initial lag before acceleration of the formation of uro'gen-I (2). An even more striking lag was observed[22] in the production of uro'gen-I (2) by deaminase from PBG (see Fig. 6); there was no lag in formation of uro'gen-III (3) from PBG when the deaminase–cosynthetase system was used.

Clearly, an intermediate substance is released into the medium when deaminase alone acts on PBG (1) or on the $^+$NH$_3$CH$_2$-bilane (9a); proof will be given later that the same intermediate is formed from both. What is its structure?

The intermediate was first generated from PBG (1) using deaminase to point A in Fig. 6 and it was then allowed to ring-close. The product was more than 99% uro'gen-I (2), showing that four PBG units had been joined head-to-tail without rearrangement. The intermediate was then generated as before but from [11-^{13}C]PBG (Fig. 2, 1b) and, after the enzymatic reaction was quenched, ^{13}C-NMR of the intermediate showed it to contain one HO^{13}CH$_2$-pyrrole residue and three methylene groups in the environment pyrrole-^{13}CH$_2$-pyrrole. These results proved[22] that the intermediate produced from PBG (1) by deaminase alone is the unrearranged hydroxymethylbilane (Fig. 4, 15), abbreviated below to HOCH$_2$-bilane. Similar ^{13}C-NMR studies showed[17] that deaminase converts the $^+$NH$_3$CH$_2$-bilane (9a) into this same HOCH$_2$-bilane (15).
Fig. 4

We can look back at the comments made earlier concerning the group X in Fig. 3; it is now clear that when deaminase acts alone on PBG, the final nucleophile is water and X = OH.

Rigorous confirmation of the HOCH$_2$-bilane structure (15) for the intermediate came from its synthesis. This presented more than the usual challenge since the half life of the HOCH$_2$-bilane in physiological conditions is only a few minutes. Synthesis was achieved[23] by generating the labile HOCH$_2$-pyrrole residue only at the penultimate stage. This synthetic HOCH$_2$-bilane (15) was chemically and spectroscopically identical with the natural intermediate. The stage was thus set for enzymatic comparisons of the natural and synthetic HOCH$_2$-bilane (15).

The roles of deaminase and cosynthetase

Deaminase. The HOCH$_2$-bilane (15) was shown to be the endproduct of deaminase action on PBG by generating the bilane as earlier to point A, Fig. 6, and allowing it to ring-close chemically. A second equivalent portion of (15) was treated at point B, Fig. 6, with additional deaminase. The two rates, from A and B, of uro'gen-I (2) formation were essentially the same. So deaminase is not an enzyme for ring-closure and, in the absence of cosynthetase, its product is the unrearranged HOCH$_2$-bilane (15)[22].

This product does not react chemically at an appreciable rate with added nitrogenous nucleophiles such as $^+NH_4$ or NH$_2$OH, but when the HOCH$_2$-bilane (15) is treated with these nucleophiles in the presence of deaminase there is essentially complete conversion into $^+NH_3CH_2$-bilane (9a) and HONHCH$_2$-bilane

(8, X = HONH), respectively. The nucleophiles are thus trapping a substance, probably enzyme-bound, which is more reactive than the HOCH$_2$-bilane (15) and can be derived enzymatically from it[22]. The properties of this species suggest that it is the enzyme-stabilised methylenepyrrolenine (16). The earlier important observations of such nucleophilic trapping[24,25] fall into place on this view.

These trapping experiments have valuable mechanistic implications but the major point is this: with the unrearranged tetrapyrrole system (15) having been built, deaminase has done its job ready for cosynthetase to play its part.

Cosynthetase. The HOCH$_2$-bilane (15) generated enzymatically to point C, Fig. 6, was treated initially with deaminase-cosynthetase and the result was dramatic[22]. Virtually instantaneous ring-closure occurred with rearrangement to produce uro'gen-III (3), Fig. 6.

Fig. 6 Formation of hydroxymethylbilane (15) from PBG by deaminase followed by ring-closure from points A, B and C: *a*, without additional deaminase; *b*, with additional deaminase; *c*, with added deaminase–cosynthetase.
It was satisfying to find that cosynthetase alone acted in the same very rapid way on the HOCH$_2$-bilane (15) to form >98% isomerically pure uro'gen-III (3); the same result was obtained whether the HOCH$_2$-bilane (15) had been enzymatically generated or chemically synthesised[23]. Table 1 gives a comparison of the two preparations and particular attention is drawn to the quantitative agreement of the kinetic data. Cosynthetase is thus the ring-closing and rearranging enzyme; its substrate is now known and is available synthetically.

Assay for cosynthetase. The foregoing results are of relevance to medical studies of certain porphyrias. In the past, no direct assay was available for cosynthetase; its presence or absence in an enzyme preparation could be crudely checked by combining it with deaminase and determining the proportion of uro'gen-III (3) in the macrocyclic products formed from PBG. The availability of synthetic HOCH$_2$-bilane (15) allows rapid, direct and quantitative assay for cosynthetase and so should allow identification of porphyria patients deficient in this enzyme.

Deaminase–cosynthetase. Bearing in mind knowledge summarised so far, there are two ways in which deaminase and cosynthetase could operate in forming uro'gen-III (3). (i) They could be completely independent enzymes such that in their natural state the HOCH$_2$-bilane (15) from deaminase is released into the medium to be picked up by cosynthetase; the two enzymes can certainly function quite independently *in vitro*. (ii) Deaminase and cosynthetase, each with its independent active site, may be closely associated by physical binding and uro'gen-III could be formed by transfer of the HOCH$_2$-bilane within the complex. The experimental distinction between (i) and (ii) is important and requires more work. It is known[21,26] that

(11)

δ (p.p.m.)

Fig. 5 ^{1}H-NMR signals from positions 5, 10, 15 and 20 of coproporphyrin-III tetramethyl ester (11) from experiment on order of assembly of the pyrrole rings; the relative positions of the signals, spread by added shift reagent, had previously been assigned[14].

deaminase and cosynthetase can bind to each other but it remains to be seen whether evolutionary pressures have selected what would be expected to be the more efficient possibility (ii); we hope that time, on our human scale, will allow the distinction to become evident.

Valuable enzymatic work in this area has been reported independently by Scott's group[27] but their chemistry and conclusions are completely different from ours; evidence from many angles[23] does not favour their view.

Table 1 Comparison of synthetic and natural $HOCH_2$-bilane (15)

	$t_{\frac{1}{2}}$ (pH 8.25 at 37 °C)	% Uro'gen-III formed by cosynthetase alone	V_{max} for cosynthetase*
Synthetic	4.0 min	>98	151
Natural	4.2 min	98	148

* μmol uro'gen produced at pH 8.25 at 25 °C per hour, per ml of cosynthetase preparation.

Present knowledge and prospects

The biosynthetic pathway which has emerged from the work outlined here is illustrated in Fig. 4. Four units of PBG (1) are assembled head-to-tail by deaminase, starting with ring A and building round to ring D to form the unrearranged bilane (8). In the absence of cosynthetase, the bilane is released into the medium as hydroxymethylbilane (15). Deaminase has then done its job; it is not an enzyme for ring-closure, although it does equilibrate the $HOCH_2$-bilane (15) with a more reactive species (probably enzyme stabilised) which has properties expected of the methylenepyrrolenine (16).

Cosynthetase then takes charge by ring-closing the $HOCH_2$-bilane (15) at high speed to form uro'gen-III (3). This involves an intramolecular rearrangement which affects only ring D and the atoms which become C-15 and C-20 of uro'gen-III (3) (see Fig. 3 for what joins to what). The most probable intermediate in this rearrangement is the spiro-system (17).

We are now seeking direct evidence for the intermediate(s) between the $HOCH_2$-bilane (15) and uro'gen-III (3) and also information about the nature of group X (Fig. 4). The recently acquired knowledge reviewed here opens the way to fascinating opportunities in the medical and enzymatic areas where exciting advances should be possible.

ARTICLE

Inverted terminal repetition in vaccinia virus DNA encodes early mRNAs

Riccardo Wittek, Ernest Barbosa, Jonathan A. Cooper, Claude F. Garon, Hardy Chan & Bernard Moss

National Institute of Allergy and Infectious Diseases, National Institutes of Health, Bethesda, Maryland 20205

Vaccinia virus DNA contains a long inverted terminal repetition of MW ~6.8 × 10⁶. A fragment of MW 6.3 × 10⁶ from this repetition has been cloned in coliphage λ and used to isolate RNA from virus-infected cells. Electron microscopy indicates that early RNAs are transcribed from the repeated sequence and cell-free translation shows that the RNAs code for polypeptides.

IDENTICAL sequences are present at the two ends of the genome of many viruses, presumably to fulfil an essential function in DNA replication[1–7]. However, the long ($\sim7 \times 10^6$ dalton) inverted terminal repetition in vaccinia virus[6,7] appears to be transcribed[7], suggesting that the region may also encode viral proteins. To investigate this interesting possibility, we have used coliphage λ to clone a fragment of molecular weight (MW) 6.3×10^6 from the end of the 122×10^6 MW vaccinia virus

genome and have used the recombinant DNA to isolate RNA from virus-infected cells. Electron microscopy indicates that early RNAs are transcribed from the repeated sequence, and cell-free translation shows that these RNAs code for polypeptides.

Length of the terminal repetition

Restriction endonuclease analyses were undertaken both to confirm the length of the inverted terminal repetition, which was estimated by electron microscopy to be of MW 6.8×10^6 daltons for the WR strain of vaccinia virus[7], and to select suitable DNA fragments for cloning. *Hin*dIII digestion of vaccinia virus DNA produces two end fragments of MW approximately 17.8 and 13.4×10^6 (ref. 7). When these were further digested with *Hin*cII and analysed by agarose gel electrophoresis, 8 of the 15 bands from the larger (*Hin*dIII B) end fragment co-migrated with 8 of the 14 bands from the smaller (*Hin*dIII C) end fragment (Table 1). Similarly, 8 common bands were detected by *Hpa*II digestion of the two *Hin*dIII end fragments (Table 1). The sums of the common *Hin*cII and *Hpa*II fragments were 6.6×10^6 and 6.2×10^6 daltons, respectively, which is consistent with their deriva-

Fig. 2 Ethidium bromide-stained agarose gel showing fragment patterns produced by cleavage of the recombinant phage DNA (track 1) and by cleavage of vaccinia virus DNA *Hin*dIII fragments B (track 2) and C (track 3) with *Eco*RI. A mixture of the two *Hin*dIII end fragments B and C was isolated from sucrose gradients[7] and the cross-links were removed by treatment with a single-strand specific DNase isolated from vaccinia virions as described previously[7,9]. One μg of octameric *Eco*RI linker (Collaborative Research) was phosphorylated with polynucleotide kinase and ligated to approximately 5 μg of *Hin*dIII fragments as described[15] except that ligation was performed at 11.5°C for 17.5 h. After ligation, linker oligomers were removed by chromatography on a Sepharose 6B column. The DNA was recovered in the void volume, extracted with phenol and precipitated with ethanol. The DNA was then cleaved with *Eco*RI and the fragments were ligated to the arms of λgt WES·λB (ref. 16) which had been purified by chromatography on RPC5. Recombinant DNA molecules were encapsidated by '*in vitro* packaging'[17] and the resulting phage were used to infect *E. coli* K12 DP50/supF (ref. 16) under P2-EK2 conditions in line with NIH guidelines for recombinant DNA experiments. Phage containing the *Eco*RI end-fragment were detected by the plaque-hybridisation technique[18] using ^{32}P-labelled *Sal*I end-fragment (MW 2.35×10^6) of vaccinia virus DNA as a probe. Positive phage plaques were picked and used to infect a 5 ml culture of DP50/supF cells. The phage were partially purified[19], after which the DNA was extracted, cleaved with *Eco*RI, and analysed on a 15 cm long 0.8% agarose gel. *Eco*RI digests of *Hin*dIII end fragments B and C, which were isolated from 0.6% agarose gels and purified by binding to glass-powder[20], were analysed on the same gel. The smallest *Eco*RI fragments of *Hin*dIII fragment B (MW ~0.52×10^6) and *Hin*dIII fragment C (MW ~0.7×10^6) have both run off the gel.

Fig. 1 Autoradiograph showing agarose gel electrophoresis of end fragments obtained by partial *Hin*cII digestion of *Hin*dIII fragments B and C. Approximately 1 μg of purified *Hin*dIII fragments B and C were digested separately with 1 unit of *Hin*cII. At 1 to 30 min after addition of enzyme, portions of the incubation mixture were removed and digestion was stopped by addition of EDTA. Samples were combined and electrophoresed on a 0.8% agarose gel. DNA fragments were transferred to nitrocellulose[8] and probed with the *Sal*I end-fragment (MW 2.35×10^6) labelled with ^{32}P by nick-translation[14]. Molecular weights of the partial digestion products were determined by comparison of their electrophoretic mobilities with those of λ and adenovirus DNA fragments of known size. B, Partial products from *Hin*dIII fragment B; C, partial products from *Hin*dIII fragment C.

tion from a 6.8×10^6 dalton terminal repetition. This was confirmed by showing that the sizes of 8 partial *Hin*cII digestion products derived from the two ends of the genome were identical. After partial *Hin*cII digestion of *Hin*dIII fragments B and C and agarose gel electrophoresis, the terminal 2.35×10^6 dalton *Hin*cII fragment and all partial digestion products containing this sequence were identified by hydridisation to a ^{32}P-labelled 2.35×10^6 dalton end fragment probe. Figure 1 reveals that the first eight *Hin*cII sites occur in the same locations in *Hin*dIII fragments B and C, thereby generating eight common bands. From this point on, the partial digestion products from *Hin*dIII fragments B and C diverged (Fig. 1). The largest common partial end fragment is 6.6×10^6 daltons in agreement with the sum of the eight co-migrating *Hin*cII fragments (Table 1). The partial digestion method was also used to show eight

Fig. 3 Ethidium bromide-stained agarose gel showing the fragment patterns produced by cleavage of the cloned DNA insert and of authentic vaccinia virus DNA with *Hpa*II. *Hind*III fragments B (track 1) and C (track 2) were isolated from 0.6% agarose gels by binding to glass powder[20] and cleaved with *Hpa*II. Recombinant phage DNA was cleaved with *Eco*RI and the 'insert' was purified and cleaved with *Hpa*II (track 3). Authentic *Eco*RI end fragment was obtained by cleavage of isolated *Hind*III fragment C from vaccinia virus DNA with *Eco*RI and isolation of the *Eco*RI end fragment. The purified fragment was further digested with *Hpa*II (lane 4). Electrophoresis was carried out in 1.4% agarose gels.
identical *Hpa*II sites at both ends of the vaccinia virus genome (not shown). Thus restriction endonuclease analyses indicated that the inverted terminal repetition is greater than 6.6×10^6 daltons.

Cloning the terminal repetition

*Hinc*II and *Hpa*II were useful for determining the minimum length of the terminal repetition because they make a large number of cuts in that region. However, to obtain a fragment for cloning, we required a restriction endonuclease that made its first cut just before the junction of the repeated and unique sequences. Screening for such an enzyme was simplified by an unusual feature of vaccinia virus DNA. Because the two strands of DNA are covalently linked at their ends[9], terminal fragments produced by restriction endonucleases can be identified by their ability to renature rapidly[10]. As anticipated, agarose gel electrophoresis showed a single rapidly renaturing end fragment when the first cut occurred within the terminal repetition whereas two end fragments were found when the first cut was beyond the 6.8×10^6 dalton repetition. From this survey, we noted that *Eco*RI produced a single 6.3×10^6 dalton rapidly renaturing end fragment from whole vaccinia virus DNA and the same size fragment on sub-digestion of either of the two large *Hind*III end fragments (Table 1; tracks 2 and 3, Fig. 2). Accordingly, the *Eco*RI end fragment was selected for cloning.

The strategy used to insert the *Eco*RI end fragment of vaccinia virus DNA into coliphage λ, detailed in Fig. 2 legend, involved cleavage of the covalently linked termini of isolated vaccinia *Hind*III end fragments with a single-strand specific DNase;

blunt-end ligation of an octameric linker containing the *Eco*RI site to the terminus; *Eco*RI digestion of the product and ligation of the vaccinia DNA fragment to λ 'arms'. After *in vitro* packaging of the recombinant DNA, *Escherichia coli* were infected and plaques were identified by hybridisation using the 2.35×10^6 dalton ^{32}P-labelled *Sal*I end fragment of vaccinia virus DNA as a probe. For further identification, the recombinant phage DNA was purified and digested with *Eco*RI. Four
Fig. 4 Autoradiograph of a polyacrylamide gel showing the polypeptides synthesised in a reticulocyte cell-free system programmed with RNA selected by hybridisation to the cloned terminal repetition of vaccinia virus DNA. Cytoplasmic RNA was purified from HeLa cells which had been infected with approximately 30 plaque-forming units of purified vaccinia virus per cell[11]. Immediate early, early and late RNA were prepared from cells infected for 4 h in the presence of $100 \mu g \, ml^{-1}$ cycloheximide, $40 \mu g \, ml^{-1}$ cytosine arabinoside or for 6 h without inhibitors, respectively. Approximately $210 \mu g$ of each RNA preparation was hybridised to 0.2 pmol of recombinant DNA immobilised on nitrocellulose filters in $300 \mu l$ of 80% formamide, 0.4 M NaCl, 40 mM PIPES pH 6.4, 1 mM EDTA and 0.1% SDS at 37°C in a shaking water bath for 18 h. At the end of the hybridisation, the filters were stringently washed to remove unhybridised RNA[21]. This consisted of three washes at room temperature with 4 ml of 10 mM Tris-HCl pH 7.5, 1 mM EDTA, 0.1% SDS, then three washes with 10 mM Tris-HCl pH 7.5, 1 mM EDTA. The filters were then washed twice using 0.4 ml of hybridisation solution lacking SDS at 37°C for 15 min and finally in 0.4 ml of 80% formamide, 40 mM PIPES pH 6.4, 1 mM EDTA at 37°C for 15 min. Hybridised RNA was eluted in 0.2 ml of water at 100°C for 2 min, and then alcohol precipitated with $20 \mu g$ of calf liver tRNA (Boehringer Mannheim). The precipitate was washed twice with 70% ethanol and dried *in vacuo*. This RNA was used to programme cell-free protein synthesis in 10-μl reactions containing message-dependent reticulocyte lysate[12,22]. Samples of each reaction (2 μl) were prepared for electrophoresis and analysed on a 9 cm long, SDS polyacrylamide (20% T, 0.33% C) gel[11,12]. An 8-h fluorographic exposure is shown. The reticulocyte lysate was programmed with tRNA only (track 4), with tRNA and 1 μg of unpurified immediate early, early or late RNA (tracks 1, 2 and 3, respectively), or with the immediate early, early or late RNA purified by hybridisation to recombinant DNA sequences (tracks 5, 6 and 7, respectively). The apparent space at ~15,000 daltons, and the compression just below it, are due to large amounts of unlabelled globin from the reticulocyte lysate. Similar polypeptides were detected when RNA, purified by solution hybridisation and isolation of the hybridised RNA on potassium iodide density gradients[23], was translated.
Fig. 5 Electron microscopic analysis of R-loop structures formed between intact recombinant DNA and early viral RNA. Recombinant DNA ($8 \mu g \, ml^{-1}$) and cytoplasmic RNA ($300 \mu g \, ml^{-1}$) from cells infected in the presence of cytosine arabinoside were incubated at 42°C for 20 h in a solution containing 70% formamide, 0.1 M Tricine buffer pH 8.0, 0.25 M NaCl and 0.01 M EDTA. Samples were mounted for electron microscopy by spreading the above mixture with no additions other than cytochrome *c* over a distilled water hypophase. Grids were rotory shadowed with platinum–palladium and examined in a Siemens Elmiskop 101 microscope at 40 kV accelerating voltage. Electron micrographs were taken on Kodak electron image plates at magnifications of 6,000. Magnification was calibrated with a grating replica (E. F. Fullam., cat. no. 1000), and contour lengths were measured with a Numonics digitiser interfaced to a Wang 2200 computer. R-loops are indicated by arrows, scale bar, 0.5 μm. In this molecule, the possibilities that there are two R-loops, one of which is twisted, or three R-loops, two of which are adjacent, could not be distinguished. A schematic representation of the map positions of hybridised RNA is also presented. VAC indicates the position of the vaccinia virus DNA insert with the orientation of the original cross-linked end.

bands were resolved by agarose gel electrophoresis (track 1, Fig. 2). Starting at the top of the gel, the first three correspond to the reannealed λ arms and the individual large and small λ arms, respectively. Significantly, the fourth band co-migrated with authentic EcoRI end fragment obtained by EcoRI digestion of the larger (track 2, Fig. 2) or smaller (track 3, Fig. 2) HindIII end fragments of total vaccinia virus DNA.

To prove that the cloned DNA is identical to authentic EcoRI end fragment from vaccinia virus DNA, the insert was separated from the λ arms and cleaved with HpaII. The HpaII fragments obtained from the cloned insert (track 3, Fig. 3) co-migrated with common HpaII fragments obtained by sub-digestion of the two HindIII end fragments from vaccinia virus DNA (tracks 1 and 2, Fig. 3) as well as with HpaII fragments obtained by digestion of authentic EcoRI end fragment also isolated from vaccinia virus DNA (track 4, Fig. 3). In addition, since the largest HpaII fragment obtained from the insert is derived from the originally cross-linked end of the genome and since the mobility of this fragment is similar to that of the HpaII fragment containing the cross-link, relatively little DNA was lost by single-strand nuclease treatment prior to cloning. The orientation of the inserted vaccinia DNA was determined by mapping the single XhoI restriction site of the EcoRI end fragment of vaccinia virus DNA within the recombinant molecule. The recombinant used in these studies has the originally cross-linked end of the vaccinia virus genome attached to the large arm of the λ vector. However, a recombinant with the opposite orientation was also identified.

Expression of inverted terminal repetition

Preliminary results[7] indicated that some sequences contained within the inverted terminal repetition are transcribed in vaccinia virus infected cells and further evidence for this was obtained by hydridisation of ^{32}P-labelled RNA to HpaII and HincII digests of HindIII fragments B and C from vaccinia virus DNA (E. B., unpublished). The cloned EcoRI fragment, however, provided a tool for isolating sufficient RNA to extend these studies. In particular, we wished to know whether RNA isolated by hybridisation to the cloned terminal repetition could serve as a messenger. Previously the message-dependent reticulocyte lysate, supplemented with calf liver tRNA, was shown to faithfully translate early and late vaccinia virus mRNA[11,12]. In those studies we found that RNA made in the presence of an inhibitor of protein synthesis (referred to as immediate early RNA) and RNA made in the presence of an inhibitor of DNA synthesis (referred to as early RNA) programmed synthesis of similar sets of polypeptides although some differences were also noted. When translating RNA extracted from cells late after infection, a new set of polypeptides was made in addition to continued synthesis of some early polypeptides.

Figure 4 shows the virtually blank endogenous incorporation of the reticulocyte lysate (track 4) whereas tracks 1, 2 and 3 show polypeptides synthesised when the cell-free system was programmed with total immediate early, early and late mRNAs. Tracks 5, 6 and 7 show polypeptides synthesised when the cell-free system was programmed with mRNAs selected by hybridisation to the recombinant DNA immobilised on nitrocellulose membranes. In contrast to the large number of total

immediate early polypeptides, only three prominent polypeptides of MWs 42,000, 19,000 and 7,500 as well as several minor polypeptides were detected using selected immediate early mRNA (track 5). Similar polypeptides, but in lesser amounts, were also made with selected early mRNA (track 6). Longer periods of fluorography revealed synthesis of small amounts of the same three prominent early polypeptides using selected late RNA (track 7); however, no unique late polypeptides were detected.

Electron microscopy was used to visualise the early RNA species. Cytoplasmic RNA, from cells infected with vaccinia virus in the presence of cytosine arabinoside, was annealed to the recombinant DNA in conditions of high formamide concentration which favours RNA·DNA over DNA·DNA hybridisation[13]. Nearly all molecules contained at least one 'R-loop' formed by partial displacement of a DNA strand; most molecules contained two or three R-loops. From contour length measurements of the recombinant DNA, it was apparent that all R-loops were located within the vaccinia virus DNA insert. A photograph of one DNA molecule containing R-loops and schematic representations of the R-loop locations on 32 separate DNA molecules are shown in Fig. 5. To confirm the orientation of the R-loops within the vaccinia virus DNA insert, HindIII was used to cleave recombinant molecules within the short λ arm. A similar distribution of R-loops was observed in an additional 40 molecules. The R-loop (mean 0.28 ± 0.07 μm) nearest to the large λ arm (that is, the end of the vaccinia genome) was clearly observed to contain a short single-strand extension in 28 of 160 molecules. In each case the single-strand projection, presumably a poly (A) tail, was located on the side of the R-loop nearer to the long λ arm. As represented in Fig. 5, the R-loops nearer to the short λ arm were variable in size (0.19–0.79 μm; mean 0.45 ± 0.17 μm) and in apparent poly (A) tail position. However, in molecules where one large R-loop was visible, the appearance suggested that two adjacent mRNAs had been transcribed from opposite strands. Direct evidence for strand switching has recently been obtained (R. W. and J. C., unpublished) by hybridisation of RNA to separated recombinant DNA strands. Of some interest was the absence of any R-loops within the 2.08 (± 0.06) × 10[6] daltons corresponding to the very end of the viral genome. A similar conclusion was also reached by failure of ^{32}P-labelled early RNA to hybridise to HpaII and HincII terminal restriction fragments from virion DNA (E. B., unpublished). Accordingly, this region of the genome appears to be transcriptionally inactive. Another point of interest was our inability to visualise R-loop structures containing intervening DNA, suggestive of split genes, such as have been found for other DNA viruses.

Conclusion

We have shown that the inverted terminal repetition in vaccinia virus DNA is divided into transcriptionally active and inactive regions and thus appears to have more than one function. Besides a putative role in DNA replication, a portion of the terminal repetition codes for several early mRNA species. Although the genome organisation of herpesvirus is quite different from that of poxviruses, evidence for transcription of repetitive sequences in that system has also been found[24].

Among X-ray transients, A0538 − 66 is unique: between June and December 1977 it was observed to undergo seven outbursts[1-3], characterized by different durations (from ~12 h to ~15 days) and peak intensities (from ~0.03 to 0·1 Crab). Most remarkably, the outbursts were all separated by an interval of either 16.7 days or a small multiple thereof. The source may be a member of the Large Magellanic Cloud (LMC) and thus one of the most luminous stellar X-ray sources known [$(L_x(2-17\,\mathrm{keV}) \simeq 8 \times 10^{38}\,\mathrm{erg\,s^{-1}})$]. No steady counterpart to the flaring source has yet been detected. We report here a reanalysis of the HEAO 1 modulation collimator (MC) data which has led to the detection of the five outbursts which occurred between August and December 1977. A uniquely precise (25 arc s) position has been obtained which excludes the previously suggested optical candidate. We have searched archive plates of the LMC and find that one of the stars in the refined error region shows variability in the B band by ~1 mag.

The first two outbursts of A0538 − 66 were observed with the Ariel 5 satellite[1], leading to a position accurate to ~0.5°, and, for one of the outbursts, a spectrum best characterized by a thermal bremsstrahlung model with $kT = 6.5$ keV and no detectable low-energy absorption ($N_H < 2 \times 10^{22}$ cm^{-2}). Both of these outbursts lasted ≤ 1 day. After the launch of HEAO 1, the LMC was under nearly constant scanning surveillance due to its location at the south ecliptic pole. Two more brief (~1 day) outbursts were detected with the HEAO 1 MC in October and November 1977, resulting in three possible source locations within or near the Ariel 5 error region[2]. Based on these four events, it was suggested that the outbursts showed a regularity in their onset that could be described by:

$$T_0 = (2443323.96 \pm 0.03) + (16.662 \pm 0.006)n$$

where T_0 is the Julian date of the onset time of the nth outburst[2]. The Ariel 5 events correspond to $n = 0$ and 1, and the HEAO 1 MC observations to $n = 6$ and 8. A search for other brief outbursts in the HEAO 1 MC data was unsuccessful, and an upper limit of 0.9 μJy was placed on the (1.5–13.5 keV) flux density of a steady component. A subsequent analysis of the HEAO 1 Large Area Sky Survey (LASS) data revealed that outbursts corresponding to $n = 3, 4$ and 11 did occur at the expected times[3]. The events at $n = 3$ and 4 lasted significantly longer than the other five; the flare at $n = 11$ occurred while LMC X − 3 was unusually bright[4].

The MC data for A0538 − 66, taken at maximum brightness according to the LASS light curve[3], were superimposed about the centre of the previous most likely error region. (For a description of the instrument and data analysis technique, see ref. 5). For this optimum set of data, significant detections of all five outbursts were obtained (Table 1), yielding five pairs of lines of position spanning 150° in position angle. These lines have only one common intersection within ~2° of the Ariel 5 error region, thus confirming that all five outbursts, in spite of their different durations and peak intensities, originate from the same

source. The five pairs of lines were combined[6,7] to yield the most likely source position:

$$\alpha(1950.0)\ 5\,\mathrm{h}\ 35\,\mathrm{min}\ 42.7\,\mathrm{s}, \qquad \delta -66° 53' 44''$$

with a 90% confidence error circle radius of 25 arc s. A finding chart of the region is presented in Fig. 1a. The northern half of the previous most likely error region (region A of ref. 2), including the suggested optical candidate[2] (star 19 of Fig. 1a), is excluded by the refined position reported here.

We have made a crude search for X-ray spectral variability by computing the hardness ratio R for each detected outburst. This is defined as the ratio of the counting rates in the 5.4–13.3 keV to 0.9–5.4 keV energy bands. This ratio is not well determined for the flare at $n = 11$ due to the low statistical significance of the detection and to confusion with LMC X − 3 in the lowest energy channel (0.9–2.6 keV). Three of the remaining four outbursts ($n = 3, 4$, and 6) are consistent with a constant hardness ratio, ($R = 0.51 \pm 0.05$; $\chi^2 = 1.8$ for 2 d.f.) and with the Ariel 5 spectral parameters. The outburst at $n = 8$ was significantly harder than the others: $R = 1.42 \pm 0.25$. Assuming negligible low-energy absorption, this corresponds to a change in the logarithmic slope of a power-law (energy) spectrum from −0.5 to +0.7. The data are, however, not sufficient to distinguish between a flattening of the source spectrum and an increase in the low-energy absorption. We note that the observed spectral change may complicate intensity comparisons between different instruments.

A search for optical variability or proper motion of the stars in the refined error region has been carried out with archival plate material at the Harvard College Observatory. The plates, taken with the 24″ Bruce doublet at Bloemfontein, South Africa, were examined with a blink comparator, and the two showing the strongest evidence for variability were subsequently measured with an iris photometer. Nine nearby stars from the photometric sequence of Dachs[8] were used for calibration. Star Q (Fig. 1a) is observed to be variable between extremes of $B \sim 14.5$ (12 November 1945; Plate no. A25156) and $B \sim 15.5$ (19 November 1941; Plate no. A22993), although the plates are not of sufficient quality for a detailed light curve to be compiled. Figure 1b shows the range of variability observed. Astrometry for stars C, D, Q and R has been carried out on plates taken 13 November 1896 (stars Q and R) and 19 November 1941 (stars C and D) and compared with the positions of the same stars on the ESO Quick Blue Survey plate (21 November 1973). Upper limits (3σ) of 0.28 arc s yr^{-1} (stars C and D) and 0.15 arc s yr^{-1} (stars Q and R) are placed on their proper motion, indicating that they are not very local objects[9].

Spectra of stars Q and R were obtained 31 July 1979 (~5 days before the extrapolated flare onset time) with the RGO spectrograph and IPCS at the 3.8m Anglo-Australian telescope. Star R shows H and He absorption lines typical of a normal O star: we estimate $V = 13.8$, $B - V = -0.2$. Star Q shows the absorption spectrum of a B-type star: we estimate $V = 15.7$,

Table 1 Dates of observations used for position measurements

Outburst no. (n)	Dates (JD − 2443000)	Detection Significance MC1 (σ)	Detection Significance MC2 (σ)	Average flux density* (μJy)
3	375.107–380.032	11.6	17.4	25
4	390.997–392.339	5.1	5.9	20
6	423.935–424.274	8.3	7.5	45
8	457.149–457.440	9.9	6.8	25
11	507.119–507.264	5.4	4.9	17

* For an assumed Crab-like spectrum averaged over 1.5–13.5 KeV; $1\mu\mathrm{Jy} = 0.242 \times 10^{-11}$ erg cm^{-2} s^{-1} keV^{-1}.
Fig. 1 Finding chart for A0538−66 prepared from Harvard College Observatory Plate no. A22993, taken 19 November 1941 with the 24-inch Bruce doublet in Bloemfontein, South Africa. (*b*), taken from Plate no. A25156 made with the same instrument on 12 November 1945, illustrates the variability of star Q by ~1 mag in the *B* band. The celestial location (±2 arc s) of star Q is:

$$\alpha (1950.0)\ 5\ h\ 35\ min\ 42.4\ s, \qquad \delta −66° 53' 39''$$

Star numbers are from the photometric sequence of Dachs[8].

$B − V = 0.0$, and conclude that it is a probable LMC member ($M_v = −3.8$ for an assumed distance modulus[10] of 18.6 and foreground extinction $A_v = 0.2$ mag). We note the similarity of this star to the optical candidate for LMC X−3 ($V = 16.9$, $B − V = −0.06$, weak Hβ emission, variable by 0.1 mag; see ref. 4 and refs therein).

Transient X-ray phenomena on time scales of seconds (for example X-ray bursts; see review in ref. 11) and months (for example classical X-ray transients; see review in ref. 12) have led to optical identifications and extensive studies of the stellar counterparts. In contrast, sources with characteristic outburst times of hours to days have been observed[13-17] but none have been positioned with sufficient accuracy for a convincing optical identification to be made (with the possible exception of H0449−55; ref. 17). Among sources exhibiting fast-transient behaviour, A0538−66 is of particular interest as its outbursts may have either hard or soft spectra, and may last hours or days. It thus spans the range of behaviour observed in other fast-transient sources, which, while possibly recurrent, are not located in a region of the sky subject to as continuous a surveillance as the LMC during the HEAO 1 mission. Several possible explanations for the behaviour of this source were considered in ref. 2, but present data do not significantly constrain possible source models. Optical and radio monitoring of star Q, especially near the expected times of X-ray outbursts, will be important in establishing variability commensurate with the X-ray periodicity and in elucidating the nature of this unusual system.

Freeze-formed silica fibres

Walter Mahler & Max F. Bechtold

Central Research and Development Department, E. I. du Pont de Nemours & Company, Wilmington, Delaware 19898

Phase separation during directional freezing of liquid systems leads to a variety of microstructures of the components due to the interplay of heat transfer, diffusion kinetics, and interfacial surface energy[1-6]. One of the more dramatic effects is the *in situ* formation of parallel fibres in directionally solidified eutectic superalloy. We report here similar morphological consequences of freezing aqueous polysilicic acid. This system is unique not only because it has an amorphous component, polysilicic acid, but this substance undergoes accelerated, concentration-dependent polymerization immediately after phase separation. As a result, it becomes insoluble, and after thawing, preserves the structure that had been conferred on it by the surrounding ice. We have explored the relationships of polymerization, composition, and freezing conditions with the morphology of the products, in particular with regard to fibre formation.

A solution of silicic acid in water (100 ml, 1 M in SiO_2) was prepared by ion exchange[7], adjusted to pH 5 with 0.3 ml 1 M NH_4OH, and placed in a 24×2.7 cm polypropylene cylinder. The silicic acid, which gelled 15 min after adjusting the pH, was allowed to age for another 30 min and was then directionally frozen by lowering the plastic cylinder into a −70 °C cold bath at 4 cm h^{-1}. After thawing, all the silica was in the form of insoluble parallel fibres with polygonal cross-section, ~0.005 cm in diameter and 15 cm long (Figs 1, 2). Fibres have been obtained from gels of this type with freezing rates from 0.3 to 150 cm h^{-1} and bath temperatures from −10° to −196 °C (ref. 8). Average fibre diameter decreases with lower silicic acid concentration, colder freezing baths, or with faster freezing rates in agreement with theoretical treatments of eutectic alloys[1-6].

Although each fibre has a unique cross-sectional geometry, the cross-section is invariant along the length of the entire fibre when freeze-formed in uniform conditions. When a cylinder of gelled silicic acid is frozen statically by cooling one end, both the thermal gradient and the freezing rate decrease as the ice-gel interface advances[9]. In these conditions, the resulting fibres are tapered (for example, 0.004 cm diameter at one end, and 0.026 cm at the other end of an 11-cm long fibre).

After drying in air at 150 °C, the composition of the fibres corresponds to $Si_3O_5(OH)_2$. The fibres are amorphous (X ray) and porous; surface area is about 900 m^2 g^{-1}, and the density measured by flotation in carbon tetrachloride–bromoform is 1.99 g cm^{-3}. The tensile strength is 86 ± 35 MPa. After heating at 925 °C for 8 h, the composition corresponds to SiO_2; surface area is decreased, the density is 2.20 g cm^{-3}, and the tensile strength is 510 ± 216 MPa. After 8 h at 1,000 °C, the average tensile strength drops to 253 MPa, and incipient crystallization can be detected; except for shrinkage, the fibre geometry remains unchanged.

Fig. 1 Scanning electron micrograph of a bundle of silica fibres bound with twine and cut with scissors. Scale bar, 100 μm. Magnification ×20.

The slower polymerization rate of 1 M silicic acid at *p*H 3 (gel time is 24 h at 25 °C) permits a wider range of product morphologies to be prepared. Fresh silicic acid, frozen and thawed promptly, reforms soluble silicic acid[10]. After ageing 1 M silicic acid 1 day at 25 °C, freezing and thawing gives insoluble imbricated flakes, roughly 0.1 cm across with parallel ridges 0.001–0.002 cm apart on one side (Fig. 3). The same morphology is observed when fresh silicic acid is frozen, aged 1 day at −10 °C, and then thawed. After 3 days' ageing at 25 °C before freezing, flakes are obtained that are accompanied by honeycomb structures and 6 days' ageing before freezing gives polygonally cross-sectioned fibres having about 550 m^2 g^{-1} surface area after drying. After ageing for about 20 days, fibres are
Fig. 2 Silica fibres. Scale bar, 100 μm. Magnification ×200.

obtained with properties equivalent to those described above made from gel at *p*H 5. The same results are obtained with gels aged 6 months. Fibres can be obtained by freezing gels that are between 0.5 and 5.0 M in SiO$_2$. However, fibre formation is precluded by the presence of more than 0.025 M salts. Featureless flakes are obtained instead.

Dilute aged silicic acid (0.1–0.5 M SiO$_2$) gives a mixture of flakes and fibres of a quite different appearance. These fibres are ~0.0002 cm in diameter and 0.2 cm long with rounded cross-sections that are not uniform along the fibre length. They are occasionally branched, and seem to be the remnants of the ridged flakes where the interconnections between ridges have thinned to the vanishing point.
Fig. 3 Ribbed flakes. Scale bar, 100 μm. Magnification ×300.

Freezing of silicic acid and other colloids has been widely discussed, but all morphological descriptions of the products have been of small particulates, specifically powders[11], flakes[12,13], ribbed flakes[14], interconnected cells[15], and granules[16,17]. Our finding that high gel strength, low electrolyte concentration, and unidirectional freezing seem to be essential for obtaining polygonally cross-sectioned fibres may have some generality. Zirconia gels prepared by dialysis have responded similarly.

A thin-film polycrystalline photoelectrochemical cell with 8% solar conversion efficiency

Gary Hodes

Department of Plastics Research, The Weizmann Institute of Science, Rehovot, Israel

Photoelectrochemical solar cells (PECs) may become an economic method for conversion of light to electricity, due largely to the simplicity of formation, and quality, of the polycrystalline semiconductor–electrolyte junction. Within the past few years, conversion efficiencies of thin-layer polycrystalline-based cells have increased from ~1% to a recently reported 7.3% for the n-GaAs/Se$_x^{2-}$ system[1]. PECs based on the CdSe-polysulphide system have been studied extensively recently. CdTe, with a band-gap, E_g, ~1.45 eV is better matched to the solar spectrum than CdSe (E_g ~ 1·75 eV), but is unstable in polysulphide solutions as a photoanode at the current densities to be expected under normal solar irradiation (>10 mA cm^{-2}). A polysulphide-based PEC is described here which uses polycrystalline layers of CdSe$_{0.65}$Te$_{0.35}$, electrodes of which are prepared by painting a slurry of the semiconductor onto a Ti substrate, and sintering. Subsequent surface treatments of these layers lead to a solar-to-electrical conversion efficiency of up to 8%, with stability comparable to the thin-layer polycrystalline CdSe/polysulphide system[2].

CdSe and CdTe form solid solutions over the entire composition range. The electrical, optical and thermoelectrical properties of these alloys have been studied, and a minimum in the band gap of ~1.35–1.45 eV (depending on crystal structure) has been found[3]. To use these alloys as photoelectrodes in liquid junction photovoltaic cells layers of the alloys were prepared by a process similar to screen printing, whereby a CdSe$_{0.65}$Te$_{0.35}$ powder (prepared by sintering CdSe and CdTe powders

Fig. 2 Spectral response of a polycrystalline CdSe$_{0.65}$Te$_{0.35}$ photoanode in polysulphide solution (1 M each KOH, Na$_2$S, S). The photocurrent is corrected for photon density (that is the spectrum compares the relative quantum efficiency with the wavelength). The shape of this response, together with X-ray diffraction data, which shows that these electrodes are of a single composition, and with lattice parameters to be expected from this composition (compared with those of ref. 6), proves that the semiconductor is indeed a homogeneous alloy.

together with a CdCl$_2$ flux) was made into a smooth aqueous paint together with CdCl$_2$, painted onto a Ti substrate and then annealed in an inert atmosphere. The resulting electrodes were etched, and tested in an aqueous electrolyte containing 1 M each of KOH, Na$_2$S and S, with a counter electrode of sulphide brass gauze[4]. The light source was either solar illumination, or a tungsten source calibrated for the CdSe$_{0.65}$Te$_{0.35}$ cells against solar illumination.

The performance of the photoelectrodes depends strongly on the etching treatment used. Figure 1 shows examples of the output characteristics for three different treatments. The dotted line represents output characteristics obtained after a HCl:HNO$_3$ etch (the usual etch for CdSe photoelectrodes). Solar efficiencies up to 5.0% have been obtained after this treatment. Etching in dilute aqeous CrO$_3$ leads to an improved open circuit voltage and solar efficiencies up to 5.5%. The same increase of the OCV can be obtained after the HCl:HNO$_3$ etch by treating the electrode surface with a solution containing CrO$_4^{2-}$ ions before immersion in the polysulphide electrolyte.

A major increase in both short circuit current and fill factor (FF) was obtained by a subsequent photoetch, whereby the photoelectrode, shorted to a carbon counter electrode, was illuminated in a dilute aqueous mineral acid solution, for example, 0.1 M H$_2$SO$_4$. After treatment with an aqueous K$_2$CrO$_4$ solution, solar efficiencies up to 8.0% were obtained (the solid line in Fig. 1 shows the performance of a CdSe$_{0.65}$Te$_{0.35}$ photoelectrode after such a treatment).

Figure 2 shows the spectral response for a CdSe$_{0.65}$Te$_{0.35}$ photoelectrode in 1 M each of KOH, Na$_2$S and S. The short wavelength cutoff can be attributed to absorption by the polysulphide electrolyte. As the photocurrent loss due to this absorption is the same for CdSe and the CdSe$_x$Te$_{1-x}$ system, the fractional loss in the case of CdSe (E_G ~ 1.75 eV) is considerably greater than for the smaller band-gap mixed compounds. This explains the much greater photocurrents obtained for CdSe$_{0.65}$Te$_{0.35}$ than for CdSe (~60% increase was typically found), compared with what would be expected from the difference in band gaps, calculated on the basis of photon intensity of the relevant sections of the solar spectrum (<40% increase). The plateau region is surprisingly flat, and the long

Fig. 1 Photocurrent–photovoltage characteristics for polycrystalline CdSe$_{0.65}$Te$_{0.35}$ electrodes in polysulphide solution (1 M each KOH, Na$_2$S, S) under 0.85 X AMI simulated sunlight. ·····, after HCl:HNO$_3$ etch, electrode area 0.22 cm^2; ---, after CrO$_3$ etch or K$_2$CrO$_4$ treatment; ——, after photoetch + K$_2$CrO$_4$ treatment, electrode area 0.55 cm^2.

wavelength cutoff is fairly sharp (considering the polycrystalline nature of the electrode), and shows an effective band gap of ~1.45 eV, similar to that of CdTe.

The output stability of the photoelectrodes in polysulphide electrolyte has been measured in various conditions. In an electrolyte 3 M each in KOH and Na_2S and 4 M in S, and at 35 °C, the photocurrent remained stable for 21 h at 20 mA cm^{-2}. After 21 h the illumination intensity was increased to give a photocurrent density of 28 mA cm^{-2}. The photocurrent decreased 3.6% (to 27 mA cm^{-2}) after a further 20 h. Another electrode, illuminated to give an initial photocurrent density of 42 mA cm^{-2}, dropped 16.8% in current output after 49 h. Note that the normal operating currents of such photoelectrodes would be less than 20 mA cm^{-2}. It has been shown that for CdSe operating in a polysulphide electrolyte, complete stability may be obtained for a certain amount of charge passed at low photocurrent densities, while at higher current densities, a large degree of instability may be manifested for the same amount of charge passed[5]. This is a consequence of the exchange between solution sulphide and selenium from the CdSe, which depends on the relative rates of the competing S^{2-} oxidation and CdSe photodecomposition reactions[2,5]. The same mechanism is to be expected at the mixed $CdSe_xTe_{1-x}$ electrodes. Therefore the actual stability of these electrodes in normal (solar) operating conditions will be considerably better than suggested by the above 'worst case' conditions.

The effect of the photoetching treatment has been found to be general for many semiconductors besides $CdSe_{0.65}Te_{0.35}$. Scanning electron micrographs of the semiconductor surface show extensive pitting of the surface by the photoetch, which therefore seems to act as a selective etch. The increased surface area resulting is clearly visible to the eye as a change from a dull grey surface to a velvet matt black one. Part of the increase in photocurrent after photoetching is probably due to a lowered reflectivity of the surface, but this cannot explain it completely, as the original surface was itself not very reflecting (~10% reflectivity). Also, the increase in the fill factor, typically by ~10%, remains to be explained. The photoetching effect and the effect of the composition of the $CdSe_xTe_{1-x}$ electrodes on their output stability will be discussed in detail elsewhere.

NH_4^+-tetraalkyl ammonium systems in the synthesis of zeolites

D. M. Bibby, N. B. Milestone & L. P. Aldridge

Chemistry Division, DSIR, Private bag, Petone, New Zealand

ZSM-5 (ref. 1) and ZSM-11 (ref. 2) are silica-rich aluminosilicate zeolites with similar two-dimensional intersecting channel structures. They are conventionally synthesised from Na^+-tetraalkylammonium (Na^+-TAA) systems at high *p*H and temperatures around 160 °C (refs 3–6). We report here what we believe to be the first use of systems free of alkali metal ions in the synthesis of the zeolites ZSM-5 and ZSM-11.

In the conventional synthesis other alkali metal ions can be used but we have found that the rate of reaction is highest with Na^+. Tetraethyl ammonium (TEA) or tetrapropyl ammonium (TPA) give ZSM-5, while tetrabutyl ammonium (TBA) forms ZSM-11. The TAA ions probably act as templates[7] and are
Fig. 1 Differential thermal analysis in one atmosphere oxygen of: *a*, precursor to ZSM-5 prepared from the NH_4^+-TPA system; *b*, precursor to ZSM-5 prepared from the Na^+-TPA system. The small endotherm at ~100 °C is due to the loss of absorbed water. The endotherm at ~340 °C and exotherm at ~410 °C are due to the decomposition of the NH_4^+ ion and the oxidation of TPA decomposition products respectively.

occluded into the structure to give precursors to the zeolites. Because of the channel size the organic ions can be removed only by thermal degradation, giving the zeolites. When the precursors are synthesised from the Na^+-TAA system, Na^+ ions remain in the zeolite for charge compensation. These must be exchanged by conventional ion exchange procedures if the H-form of the zeolite is required. This form has considerable potential for catalysing the conversion of oxygen-containing organic compounds, particularly methyl alcohol, to hydrocarbons[8,9].

For our present experiments we used NH_4^+-TAA systems which produce precursors containing NH_4^+ ions for charge compensation. When the precursors are heated to remove the occluded organic ions the NH_4^+ ions also decompose, giving a direct route to the H-form of the zeolite. This is shown by differential thermal analysis (Fig. 1). As the temperature is increased, the initial reaction is the decomposition of the NH_4^+ ion to give NH_3 and H^+. This is followed by decomposition of the TAA to give the H-form of the zeolite directly. A further advantage of NH_4^+-TAA systems is that the reaction stops with the formation of the zeolite, whereas in Na^+-TAA systems the zeolite is only an intermediate and the final reaction product is α-quartz. Crystals produced in the NH_4^+-TAA systems differ slightly in morphology from those produced using Na^+-TAA systems[1,2]. The ZSM-5 crystals are often twinned. The ZSM-11 crystals are the same ovate shape as those produced in the Na^+-TAA system, but are about five times longer, being up to 10 μm long.

A typical preparation for H-ZSM-5 is: SiO_2, 0.0655 M; Al_2O_3, 0.000205 M; TPA hydroxide, 0.008 M; NH_4OH, 0.15 M; H_2O, 1.0 M; heated at 160 °C under autogeneous pressure for 3 days. The SiO_2 has to be in an active form, such as silicic acid or colloidal SiO_2, and Al_2O_3 can be supplied as $Al(OH)_3$. When low Na-content reagents are used in the NH_4^+-TAA system, H-ZSM-5 and H-ZSM-11 can be prepared containing 1 p.p.m. Na. We have found approximately the same reaction rates and product yields in these Na^+-free NH_4^+-TAA systems and in the Na^+-TAA systems, and do not believe that Na^+ plays an essential part in the NH_4^+-TAA systems.

Other zeolites which have been synthesised in single-base systems free of alkali metal ions are analcite, faujasite, type A and harmotome in systems containing NH_4OH only or tetramethyl ammonium (TMA) only[10], and sodalite[11] and gismondine[12] in systems containing TMA only. However, the Na^+

contents of these systems were not reported, and may have been of significance as it has been found[13] that 'trace' amounts of Na are necessary to initiate crystallisation of some zeolites.

Silicalite-1[14] and silicalite-2[15], the aluminium-free analogues of ZSM-5 and ZSM-11 respectively, differ from the zeolites in that no charge compensating cations are incorporated into the structure. Their syntheses differ in some minor respects from those of the zeolites. We find that the silicalites can be prepared using TAAs only, although the reaction proceeds very slowly. However, we have had no success in preparing the zeolites in the presence of TAAs only. Silicalite-2 cannot be prepared in the presence of any alkali metal ion, although it is claimed that the corresponding zeolites can be synthesised using the Na^+-TBA system[5].

Note that ZSM-5 can also be produced using the Na^+–primary amine system[16]. However, when the Na^+ is replaced with NH_4^+ the rate of reaction is very much less and it is possible that trace amounts of Na^+ ($\sim0.01\%$) are catalysing the reaction.

Clinoenstatite in boninites from the Bonin Islands, Japan

Keiichi Shiraki*, Naoshi Kuroda†, Hayaomi Urano‡ & Shigenori Maruyama§

* Department of Earth Sciences, Nagoya University, Nagoya 464, Japan
† Institute of Geoscience, Shizuoka University, Shizuoka 422, Japan
‡ Department of Earth Sciences, Aichi University of Education, Kariya 448, Japan
§ Department of Earth Sciences, Toyama University, Toyama 930, Japan

Highly magnesian andesitic lavas were considered a rare and unusual rock type, before boninites proved to be so extensive among the Tertiary volcanic rocks in the Bonin–Mariana region[1–5] and some ophiolitic basalts[6,7]. Protoenstatite is also a rare mineral and its terrestrial occurrence has been confined to the high-Mg andesites from Cape Vogel, eastern Papua[8], and the Mariana Trench[3]. Some boninites from the Bonin Islands were found to contain abundant multiply-twinned clinoenstatite (inverted protoenstatite) with or without olivine. The clinoenstatite, coexisting with olivine with a similar forsterite content to that in the mantle, shows that protoenstatite crystallized later than the olivine, whereas in the olivine-free, clinoenstatite-bearing rock which has more SiO_2 than the clinoenstatite-bearing or -free boninites with olivine, the protoenstatite may have been the liquidus mineral. We show here that the presence of inverted protoenstatite in the Bonin Islands confirms our earlier suggestion[1,9,10] that boninites may have been formed by extensive partial melting of hydrous peridotite at relatively low pressures and rapid quenching from high temperatures at shallow depths.

The Bonin or Ogasawara Islands, which form the outer arc of the Idu–Mariana island arc in the Western Pacific, comprise three island groups: Chichi, Haha and Muko, which consist predominantly of volcanic rocks of Eocene to Oligocene age. The central Chichi-jima group is composed of a sequence of lower boninite pillow lavas and upper andesite or dacite breccias, on which late Oligocene limestone rests unconformably. The Haha-jima group, lying some 50 km south of Chich-jima, has a basalt–andesite–dacite suite with tholeiitic affinities of Eocene age, but boninite has never been found[2]. We have shown[11] that Muko-jima, ~70 km north of Chichi-jima, is made up largely of boninite pillow lavas and breccias containing occasional clinoenstatite. We found pillow lavas having more than 5 modal % clinoenstatite from Uguisu-hama, Muko-jima; Yoake-daira, Chichi-jima; and Kasa-yama, Chichi-jima. Komatsu also reported[12] some clinoenstatite-bearing boninites from Chichi-jima and Muko-jima.

The pillow lava from Uguisu-hama of Muko-jima contains abundant, large, dull white phenocrysts of clinoenstatite up to 10 cm long in the central part of the pillow, together with bright green bronzite phenocrysts up to 3 cm long. Olivine is very rarely present, having completely altered to pale brown or green products and carbonates. The rim is glass-rich and fine-grained; most phenocrysts are <1 mm in size. Its mineral proportions are: (modal %) clinoenstatite phenocrysts 1, orthopyroxene phenocrysts and microlites 16, clinopyroxene (augite and pigeonite) microlites 35, and glass 48. The whole rock analysis (Table 1, column 1) shows high SiO_2 content relative to clinoenstatite-free boninites (Table 1, columns 3 and 4). Electron probe analyses of the clinoenstatite phenocrysts ($\alpha_{min} = 1.660$; $2V_z = 38$–$48°$) reveal the highest Mg/Fe ratio and the lowest CaO, Al_2O_3 and Cr_2O_3 content in those from the boninites, whereas the orthopyroxene phenocrysts ($2V_x = 71$–$94°$) have nearly the same composition as other boninite orthopyroxenes (Table 2 and Fig. 1). CaO, Al_2O_3 and Cr_2O_3 contents in the clinoenstatite increase with decreasing Mg/Fe ratio.

1, Clinoenstatite-bearing rock, rim of pillow, Uguisu-hama, Muko-jima.
2, Clinoenstatite-bearing boninite, pillow breccia, Kasa-yama, Chichi-jima.
3, Clinoenstatite-free boninite, centre of pillow, Tsuri-hama, Chichi-jima.
4, Olivine-bronzite andesite, centre of dyke, Hatsune-ura, Chichi-jima.

The boninites from Yoake-daira and Kasa-yama of Chichi-jima have similar general petrographic characteristics. Both rocks contain prominent phenocrysts of both olivine and clinoenstatite together with orthopyroxene phenocrysts. The phenocrysts are set in a groundmass composed of ortho- and clino-pyroxene microlites and glass.

The clinoenstatite-bearing boninite from Yoake-daira is the most olivine- and clinoenstatite-enriched so far observed, consisting of 10% olivine, 11% clinoenstatite, 29% orthopyroxene, 25% clinopyroxene and 25% glass and others. The olivine phenocrysts of 0.5–3 mm across are consistently more magnesian ($Fo_{90–91.5}$) than those from the clinoenstatite-free boninites ($Fo_{87–89.5}$) (ref. 13); their $2V_x$ values are high, ranging

1, Large clinoenstatite phenocryst, centre of pillow, Muko-jima. 2, Clinoenstatite phenocryst, rim of pillow, Muko-jima. 3C, M, Core and margin of rim clinoenstatite around olivine (analysis 4), Yoake-daira. 4C, M, Core and margin of olivine adjacent to clinoenstatite (analysis 3), Yoake-daira. 5E, B, Clinoenstatite and bronzite of composite crystal, Yoake-daira. 6E, B, Clinoenstatite and bronzite of composite crystal, Kasa-yama. Mineral analyses were done on a JXA-5A electron microprobe at Nagoya University.

from 89 to 97°, compared with other boninite olivines ($2V_x$ = 86–93°) (ref. 10). Clinoenstatite occurs as: (1) discrete phenocrysts usually 0.5–3 mm long, rarely reaching 1 cm; (2) rims around the olivine phenocrysts; and (3) composite crystals with bronzite. Some of the phenocryst clinoenstatites have higher Mg/Fe ratio than the coexisting olivine phenocrysts, although the rim clinoenstatites are generally lower in Mg/Fe than the olivine. Note that the Mg/Fe ratio is higher in a core (Table 2, column 3C) of a large rim clinoenstatite (0.5 mm across) than in the adjacent olivine (Table 2, column 4), whereas it is lower at the margin (Table 2, column 3M) immediately adjacent to the olivine. In the composite crystals clinoenstatite is richer in Mg and Si, and poorer in Fe, Mn, Ca, Al, and Cr than bronzite, as already shown[8,14]. The rock includes the most magnesian orthopyroxene ($2V_x$ = 101°; Fig. 1) analysed in the boninites.

The clinoenstatite-bearing boninite from Kasa-yama is less olivine- and clinoenstatite-enriched, having 4% olivine and 7% clinoenstatite. The size of those phenocrysts is small, mostly <0.5 mm. No fresh olivine was observed. The clinoenstatite

Fig. 1 Compositions of phenocryst clinoenstatites (○), rim clinoenstatites (◎), composite crystals (●), orthopyroxenes (◦), and olivines (+) in clinoenstatite-bearing boninites plotted on the pyroxene quadrilateral. Adjacent grains are connected by lines.

(α_{min} = 1.661) is the least magnesian among the three clinoenstatite-bearing rocks. The whole rock chemical composition (Table 1, column 2) is not very different from that of the clinoenstatite-free typical boninite, although it may be slightly higher in SiO_2 at a given MgO content.

In the clinoenstatite-bearing boninites of Chichi-jima the distribution of Mg and Fe between the olivine and rim clinoenstatite suggests that the latter formed by reaction of olivine and magma, although some of the phenocryst clinoenstatite may have crystallized almost simultaneously with olivine. On the other hand, for the clinoenstatite-bearing rock of Muko-jima in which olivine is virtually absent, the large clinoenstatite phenocrysts richest in Mg seem to have been the liquidus phase instead of olivine. The crystallization of the clinoenstatite (protoenstatite) may have been promoted by the high SiO_2 content in the magma and/or the release of water from the water-saturated magma at a shallow depth. The clinoenstatite-bearing boninites would be generated at higher temperatures than the clinoenstatite-free boninites.

All the clinoenstatite-bearing rocks from the Bonin Islands, Cape Vogel and the Mariana Trench have high MgO contents, >11 wt%. Judged by the experimental studies[15,16], high temperatures at least 1,200 °C at relatively low pressures (< 15 kbar) would be required to produce such highly magnesian and siliceous liquids even in water-saturated conditions. In many island arcs it seems unlikely that temperatures above or near the descending slab are high enough to generate the clinoenstatite-bearing rocks. A possible site may be a spreading ridge or an island arc with a steep geothermal gradient by previous magma generation where water liberated from the underlying subducted oceanic crust can be introduced.

Palaeozoic plants from Saudi Arabia

A. A. El-Khayal*, W. G. Chaloner† & C. R. Hill‡

Cromwell Road, London SW7 5BD, UK

A fossil flora recently discovered in the central part of Saudi Arabia is reported here. This represents the first assemblage of plants of Permo-Carboniferous age in the Arabian peninsula. The assemblage is of interest in showing affinity with contemporaneous northern Euramerian floras rather than those of Cathaysia or Gondwanaland to the east and south of Arabia.

More than 1,000 specimens were collected from an exposure alongside the Unayzah to Buraydah road, in the town of Unayzah (Fig. 1). The plants are preserved as impressions in a 5–20-cm limonitic shale band within a sequence of beds of alternating sand and shale, close to the base of the Khuff Formation. The Khuff has been tentatively assigned to the Upper Permian on faunal evidence; the Lower Khuff fauna was collected between 40 and 72 m above the base of the Khuff and that of the Upper Khuff, collected from 2 to 28 m below the top of the formation[1].

No rocks of Carboniferous or early Permian age have yet been recognized as occurring in outcrops in the Arabian peninsula, although strata dated as Carboniferous on palynological evidence have been recognized[2] in sub-surface occurrence. Powers et al.[1] reported Lepidodendron and Dadoxylon as having been recorded from outcrop of the Khuff Formation, but no documentation for these records or other details are given. Carboniferous beds with plant fossils are known from Syria[3] and Iran[4].

The most abundant plant in the assemblage from Unayzah (occurring on approximately two-thirds of the rock specimens seen) is a species of Pecopteris (Fig. 2f). Some of this material bears sporangia (Fig. 2c) and these indicate an affinity with the Dizeugotheca–Acitheca complex. Fronds of similar aspect (Pecopteris hemiteloides, P. unitus) are widely known from European and Cathaysian late Carboniferous and Permian floras, but also occur in some of the so-called mixed floras of Gondwanaland (for example, that at Wankie, Rhodesia[5]).

Of similar abundance to the Pecopteris are strap-shaped leaf fragments up to 5 cm broad, with fine parallel venation, resembling Cordaites principalis (Fig. 2a). This species occurs widely in the Northern Hemisphere late Carboniferous and early Permian. The third most abundant species is Annularia stellata (Fig. 2b). This species of calamite foliage is reported widely in North America and Europe, and also from the Cathaysian flora[6,7]. The leaves are evenly spaced in their whorls, unlike the characteristically Cathaysian genus Lobatannularia, which has a distinct segregation of leaves of each whorl into two opposed groups. The Arabian leaves show features of structural detail which uniquely characterize this species; a broad strip of longitudinal striations overlies the midrib, and is flanked by broad zones of transverse striations[8].

In addition, there are other fern-like leaves, such as Validopteris, with pinnae about 20 mm broad. Other pinnae of similar dimensions are determined, as cf. Marattiopsis (Fig. 2d,e). Attempts to extract spores from the Unayzah matrix and attached sporangia have failed.

The plants from Unayzah suggest an age not greater than Westphalian (late Carboniferous), particularly on the association of Annularia, Cordaites and the abundant Pecopteris, and the occurrence of Annularia stellata further suggests that the flora is not younger than early Permian. Marattiopsis, however, has recently been described from the late Permian of eastern

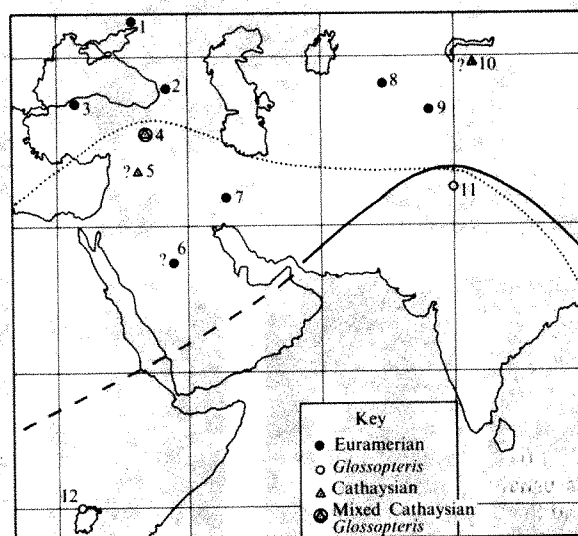
USSR[9] and this genus is otherwise only recorded from Triassic and younger Mesozoic rocks in which it is a characteristic element of northern floras. The plant assemblage described here, taken as a whole, favours an age between late Carboniferous and early Permian; if this age is sustained by further evidence, this Arabian Marattiopsis will constitute the oldest record of the genus.


Fig. 1 Fossil plant occurrences relevant to the Unayzah flora, of Carboniferous to Permian age. 1, Donbass, USSR (Carboniferous)[10]; 2, Caucasus Mts (Carboniferous)[10]; 3, Zonguldak, Turkey (Carboniferous)[10]; 4, Hazro, Turkey (late Permian)[13]; 5, Ga'ara, Iraq (late Permian)[12]; 6, Unayzah, Saudi Arabia (late Carboniferous–early Permian); 7, Chal-i-Sheh, Iran (Carboniferous)[4]; 8, Uzbekistan, USSR (Carboniferous)[10]; 9, Fergana region, USSR (Carboniferous and early Permian)[10]; 10, Malajsary, USSR (Permian)[10]; 11, Kashmir (Carboniferous and early Permian)[10]; 12, Entebbe, Uganda (Permo-Carboniferous)[11]. The two boundary lines indicate the northernmost limits of the Glossopteris flora according to Wagner[13] (· · · ·) and W.G.C. and Lacey[11] (- - - - - and ——). The question marks beside localities 5, 6 and 10 relate in each case to uncertainty in the assignment to the floral province indicated by the symbol.

Saudi Arabia has hitherto represented a blank area on palaeogeographic maps of Palaeozoic floras[10,11]. The nearest records of more or less contemporaneous floras are those of Iraq[12] (late Permian, Fig. 1:5), Iran[4] (Carboniferous, Fig. 1:7) and Turkey[13] (late Permian, Fig. 1:4) to the north, the Glossopteris floras at Entebbe (Permo-Carboniferous, Fig. 1:12) 3,000 km to the south, and Kashmir (Permo-Carboniferous, Fig. 1:11) at a similar distance to the north-east. Palaeogeographic reconstructions of Permo-Carboniferous land masses based on palaeomagnetic evidence generally show the Arabian peninsula in juxtaposition with the African block, much as in its present configuration, but lying to the south of the Tethyan Gulf, and hence contiguous with the land mass occupied by the Glossopteris flora of Gondwanaland to the south and west. The Unayzah flora comes from a region which has hitherto been considered[11] to include the boundary of northern and Gondwana floras. The outlying record of Glossopteris at Hazro (Fig. 1:4) is made the basis for the northern boundary of the Glossopteris flora by Wagner[13] (dotted line, Fig. 1), but W.G.C. and Lacey[11] query the validity of this record and show a more southerly position for this boundary (solid and broken lines, Fig. 1). The geographical significance of the Saudi Arabian flora therefore lies in the extent to which it shows clear affinity with the major floral provinces around it, and particularly in the
Fig. 2 Plant fossils from the base of the Khuff Formation, Unayzah. *a*, *Cordaites* cf. *principalis* (Germar), ×0.5; *b*, *Annularia stellata* (Schlotheim) ×0.9; *c*, Fertile *Pecopteris* ×4.7; *d*, *Marattiopsis* sp. ×5.4; pinna midrib at right, band of synangia at left, with intervening lamina between; *e*, the same, showing details of synangia on two adjacent pinnae, ×2.2; *f*, *Pecopteris* cf. *hemiteloides* (Brgt.) Stur., ×3.1. These specimens are deposited in the Geology Department of Riyadh University.

extent to which it may help clarify the northern boundary of the Gondwana province. Based on the present flora, it is clear that the most abundant and securely determined genera *Annularia*, *Pecopteris* and *Cordaites* are widespread throughout the Euramerian and Cathaysian provinces, whereas the *Marattiopsis*, if correctly determined, is known from more or less contemporaneous rocks only in eastern USSR. Apart from this taxon, the assemblage would conform with those of the Euramerian province within this period of time. In relation to the neighbouring floras of comparable diversity and age in Iraq[12] (Fig. 1:5) and at Hazro in Turkey[13] (Fig. 1:4), the lack of genera characteristic of Gondwana and Cathaysian floras is significant because the neighbouring, although probably younger, Permian floras seem to contain these elements, but occur well to the north of Unayzah. Taken at face value, the plants from Unayzah would otherwise suggest that the northern boundary of the Gondwana flora lies somewhere to the south of the central part of the Arabian peninsula at that time.

Cytotoxic T-cell response to H–Y in 'non-responder' CBA mice

Arno Müllbacher & Mary Brenan

Transplantation Biology Section, Clinical Research Centre, Watford Road, Harrow, Middx HA1 3UJ, UK

Murine cytotoxic T-cell (T_c cell) responses to various antigens are controlled by immune response genes (Ir) mapping in the major histocompatibility complex (H–2). Both helper T cells, controlled by I region-coded genes, and T_c cells, controlled by K/D antigens, are necessary for a positive response. An H–2-restricted T_c-cell response to the male specific minor transplantation antigen (H–Y) can be elicited in B10 (H–2^b) female mice primed with syngeneic male spleen cells intraperitoneally (i.p.) or intravenously (i.v.), or by skin grafting followed by restimulation *in vitro* in mixed lymphocyte culture (MLR) with male cells[1]. CBA (H–2^k) mice do not respond by these routes of *in vivo* priming, and this was thought to be due to a lack of permissible Ir genes for helper function[2]. However, we now report that subcutaneous hind-footpad (fp) immunisation of 'non-responder' CBA mice with syngeneic male cells changes them to responders, a result which argues against a generalised Ir gene-controlled helper defect.

We tested B10 female and (CBA × B10)F_1 (k × b) female spleen cells for their ability to mount an H–2-restricted T_c-cell response to H–Y *in vitro* after priming with male cells *in vivo*. B10 females were primed with 10^7–2×10^7 non-irradiated or irradiated male spleen cells, administered i.v. or i.p.; (k × b) female mice were primed with either 2×10^7 CBA male or
Fig. 1 Cytotoxicity of B10 and $(k \times b)F_1$ H–Y immune T_c cells. B10 female mice were given 1–2×10^7 unirradiated B10 male cells i.v. (●) or i.p. (○). $(k \times b)F_1$ mice were given either 2×10^7 2,000R irradiated CBA (▲) or B10 (■) male spleen cells i.v. Spleens of individual animals were removed at least 2 weeks after immunisation and cell suspensions prepared in RPMI supplemented with 10% heat-inactivated fetal calf serum (FCS), 2×10^{-5} M 2-mercaptoethanol and penicillin/streptomycin, and cultured at 2×10^6 cells ml^{-1} for 5 d at 37 °C and 10% CO_2 with equal numbers of 2,000R-irradiated male stimulator cells homologous to the immunising cells. Thereafter, graded numbers of spleen cells were tested for cytotoxic activity against 2×10^4 ^{51}Cr-labelled concanavalin A (Con A)-stimulated B10 male and CBA male lymphoblasts. (Spleen cells cultured for 24 h in RPMI supplemented with 10% FCS plus Con A at a concentration of 4 μg ml^{-1}, cell concentration 5×10^6 per ml.) The cytotoxicity assay was carried out in triplicate in microtitre plates over a 3-h period with s.e.m. < 3%. The range of spontaneous ^{51}Cr release was 8–20%. % Specific lysis was calculated according to the formula: % specific lysis = (experimental release – medium release/maximum release – medium release) × 100. K:T ratio, ratio of killer to target cells.

2×10^7 B10 male spleen cells irradiated with 2,000R to avoid a possible allogeneic effect and boosted *in vitro* with the same antigen as used for priming. As can be seen in Fig. 1, $(k \times b)$ H–Y immune T_c cells can lyse B10 male targets specifically when primed and boosted with B10 male cells and lyse CBA male targets when primed and boosted with CBA male spleen cells; these results show that H–2^k plus H–Y can be recognised by T_c cells in an immunogenic fashion, a result also shown by others[1,3]. No differences could be detected in the B10 response when priming was carried out by different routes of immunisation, i.v. or i.p.
Fig. 2 Cytotoxicity of CBA H–Y immune T_c cells. CBA female mice were given 1–2×10^7 syngeneic non-irradiated male spleen cells i.v. (■), i.p. (▲) or fp (●). Spleen cells were boosted *in vitro* 5 weeks after priming, and assayed for cytotoxicity on CBA female, CBA male and B10 male targets as described in Fig. 1 legend.

The evidence for H–2^k plus H–Y association led us to investigate the possibility that H–2^k female mice can respond to H–Y when primed with CBA male cells. The two approaches taken were various doses of cells and different routes of administering cells. The results of the latter studies are shown in Fig. 2. CBA female mice primed i.p. or i.v. with syngeneic male spleen cells could not be boosted *in vitro* to generate an anti-H–Y response. This occurred over a dose range of 10^5–10^8 male spleen cells per mouse for priming and is in contrast to the results obtained with B10 and $(k \times b)$ mice. On the other hand, fp inoculation of 1×10^7–2×10^7 CBA non-irradiated male spleen cells into CBA female mice resulted in the generation of a secondary *in vitro* T_c-cell response of equal strength to that obtained with B10 mice after i.v. or i.p. priming. The response is H–2 restricted and H–Y specific.

From the large number of CBA mice tested which gave a good H–Y-specific response, only one also caused significant cross-reactive lysis of male and female B10 targets. It is not known whether this reflects true cross-reactivity by one population of T_c cells or whether different populations are responsible for the result.

Neither spleen cells of CBA female mice primed with $(k \times b)F_1$ male cells i.v. (to generate possible help *in vivo* through an allogeneic effect) nor spleen cells from lethally irradiated CBA male mice reconstituted with CBA female spleen cells for more
Fig. 3 Kinetics of anti-H–Y response in CBA mice. CBA mice primed as described in Fig. 2 legend were boosted *in vitro* 6–44 d post-priming and tested for cytotoxic activity on male (closed symbols) and female (open symbols) CBA lymphoblast targets. Values of 10:1 killer to target ratios from titration curves were used (details as in Fig. 1 legend).

than 2 weeks, could be boosted *in vitro* to generate an H–Y-specific T_c-cell response. Thus, only fp immunisation could generate a memory T_c-cell population specific for H–Y in H–2^k mice. A further difference between the response of B10 mice and CBA mice to the H–Y antigen lies in the time of appearance of the 'memory' T_c-cell pool in the spleens of primed animals.

Optimal or near-optimal responses in B10 can be obtained 2 weeks after priming, whereas with CBA mice, optimal results are only obtained 4–5 weeks after fp priming, although significant lysis is apparent after 2 weeks (Fig. 3). No responses were obtained at any time following i.v. or i.p. priming of CBA mice.

Our studies thus demonstrated that CBA mice are responders to H–Y antigen if they are immunised through the footpad and tested more than 4 weeks after immunisation.

These results are at variance with the interpretation of data obtained with H–2^k mice in chimaeric studies[2,4,5], in which it was suggested that H–2^k mice genetically lack the ability to generate H–Y-specific helper cells necessary for a T_c-cell response to H–Y, due to non-permissive Ir helper genes. This is in contrast to H–2^b mice, which apparently possess a permissive Ir helper gene.

As we have shown that mice of H–2^k haplotype can respond clearly to H–Y with a T$_c$-cell response, it must be postulated that T-helper cells are not necessary for the generation of a T$_c$-cell response to H–Y, at least, not after fp immunisation, or that i.v. and i.p. immunisation provides inadequate antigen presentation or induces a suppressor mechanism in H–2^k mice. We consider a lack of helper cell requirement unlikely, as helper T cells have been demonstrated both in H–2-restricted responses to viral antigens[6] and in alloresponses[7]. Evidence for a suppressor mechanism in the antibody response to hen egg lysozyme has recently been shown, where a B10 non-responder after i.p. immunisation becomes a responder after fp immunisation[8]. Footpad immunisation may be physiologically a more natural route of priming and may be a very effective mechanism of antigen presentation, involving lymph node T-cell subsets, such as the T-initiator cells described by Cohen and Livnat[9] capable of recruiting T$_c$-cell precursors or helper precursors. The difference in kinetics of the CBA fp response to the (k × b) i.v. response suggests a different mechanism is involved in eliciting a T$_c$-cell response to H–2^k plus H–Y.

Expression of human α-globin genes in hybrid mouse erythroleukaemia cells depends on differentiated state of human donor cell

A. Deisseroth, U. Bode, J. Fontana & D. Hendrick

Experimental Hematology Section, Pediatric Oncology Branch, National Cancer Institute, National Institutes of Health, Bethesda, Maryland 20205

We have developed a system which can be used to study the mechanisms that may govern the expression of human α-globin genes in human erythroid and non-erythroid haematopoietic cells[1,2]. Human chromosome 16, which has been shown to bear the human α-globin genes[3], is introduced by cell fusion into mouse erythroleukaemia (MEL) cells to generate continuously proliferating cell lines that retain permanently the human α-globin genes. We have shown that hybrid diploid MEL cells with human α-globin genes from erythroid donor cells express these genes fully through globin chain synthesis, while hybrid diploid MEL cells containing human α-globin genes from non-erythroid human haematopoietic donor cells contain very low levels of human α-globin mRNA and no detectable human α-globin chains. The levels of human α-globin mRNA in these hybrid cells were found to depend on factors present in the MEL recipient cell as well as on the differentiated state of the human donor cell, suggesting that this system may be suitable for characterisation of mechanisms governing haematopoietic differentiation in man.

We used normal fresh human haematopoietic cells as donor cells rather than established or transformed cell lines of fibroblasts or leukaemia cells. The Friend MEL cell was chosen as the recipient cell because it is committed to the expression of mouse globin genes; incubation of these cells in dimethyl sulphoxide (DMSO) increases cytoplasmic levels of mouse globin mRNA 50-100-fold (refs 4–6).

To ensure that the expression of the human globin genes in the hybrid MEL cells reflected the differentiated state of the donor

cells, we introduced the human genes by cell fusion because this does not alter the position of the genes in the donor genome, and the potential for alterations in the structure of the genes can therefore be minimised.

Hybrid cells derived by fusion of MEL cells and human haematopoietic donor cells lose human chromosomes during continuous culture. The biased loss of human chromosomes coupled with selection, based on the marker adenine phosphoribosyl transferase (APRT), for human chromosome 16 (refs 7, 8) which contains the human α-globin gene in man[3], facilitates the isolation of cloned hybrid MEL cells which differ only in the cellular origin of this human chromosome.

We have reported that hybrid MEL cells bearing human α-globin genes derived from erythroid cells (populations of human marrow cells dominated by erythroid cells) fully express those genes[1,2]. We have also shown that four independently derived hybrid cell clones which retain a tetraploid complement of MEL chromosomes ($\sim$80 mouse chromosomes) as well as human α-globin genes on human chromosome 16 from non-erythroid human haematopoietic donor cells, contain detectable levels of human α-globin chains[7]. Because these latter hybrid cells contained human chromosome 16 in the absence of all other human chromosomes, these studies showed that the only human chromosome which must be present in hybrid MEL cells
Fig. 1 Metaphase spread of hybrid cell derived by fusion of diploid MEL cells with non-erythroid human haematopoietic cells stained by Glemsa–trypsin banding (*a*) and Hoechst 33258 (*b*). Hybrid cells were isolated in alanosine-adenine medium which is lethal to unfused APRT-deficient MEL cells and promotes the growth of hybrid cells which have retained human chromosome 16[2,7]. Human cells used for fusion were isolated from peripheral blood of donors by Ficoll–Hypaque centrifugation[9]. These cells contained less than 1/50,000 cells which stained positive for haemoglobin with benzidine[7], and are known to contain less than 1/5,000 erythroid committed precursor cells[10]. Neither we[7] nor others[11,12] have detected human α-globin mRNA in such populations of mononuclear human cells or in leukaemia cell lines of human origin with markers of myeloid or lymphoid differentiation. Thus our population of donor cells had no detectable haemoglobin or human α-globin mRNA, and was dominated by at least a 3–4-log excess of non-erythroid human haematopoietic cells. Thirty-five metaphase spreads of hybrid diploid MEL cells with non-erythroid human α-globin genes were analysed by incubating log phase cells in colchicine, exposing successively to hypotonic and fixing media and spreading on washed glass slides as before[3,7]. Such slides were then exposed to trypsin and Giemsa stain so as to generate banding patterns specific for each of the human and mouse chromosomes[7,13,14]. Each of the 35 metaphase spreads was photographed, destained in fixative, and exposed to the fluorescent dye Hoechst 33258, which generates a uniform light fluorescence in human chromosomes, but an uneven fluorescent pattern in most mouse chromosomes, being very intense in the region of the centromere. An example of such a sequentially stained metaphase spread of hybrid cell no. 3 is shown here. Human chromosome 16 is indicated by the arrow. Although this hybrid MEL cell contains a near diploid complement of MEL chromosomes and human chromosome 16, it has lost most of the other human chromosomes, as is the case for most hybrid cells derived by fusion of MEL cells with human haematopoietic cells.

Table 1 Chromosomal constitution of hybrid MEL cells

Property measured	Hybrid cell no. 1 (human erythroid × diploid MEL)	Hybrid cell no. 2 (human non-erythroid × diploid MEL)	Hybrid cell no. 3 (human non-erythroid × diploid MEL)	Hybrid cell no. 4 (human non-erythroid × tetraploid MEL)
(A) No. mouse chromosomes	37	39	39	81
(B) Human chromosomes				
4	20	0	0	0
5	50	0	0	0
6	60	0	0	0
16	80	100	100	100
21	0	0	11	0
22	0	0	22	0
(expressed as % of metaphase spreads analysed)				
(C) poly ($A+$) cytoplasmic RNA / Human α-globin cDNA	1,050	ND	3,000	3,999
(D) Relative level of human α globin mRNA	1/350	ND	1/1,000	1/1,333
(E) Relative level of mouse globin mRNA	1/175	ND	1/22	1/100
(F) Human α globin mRNA / Mouse globin mRNA (ratio of previous 2 ratios)	0.5	ND	0.02	0.08
(G) Ratio of $\frac{\text{human } \alpha}{\text{mouse } \alpha}$ globin genes	1/2	1/2	1/2	1/4
(H) Human α globin mRNA / Mouse globin mRNA (corrected to the ratio of $\frac{\text{human } \alpha}{\text{mouse } \alpha}$ globin genes found in a diploid hybrid MEL cell)	0.5	ND	0.02	0.16
(I) Human α globin chains	Present	Undetectable	Undetectable	Present

APRT, chromosomes and globin chains of hybrid populations no. 1 and no. 4 were analysed as before[2,7]. In all cases, chromosomal analysis is based on more than 25 metaphase spreads per cell line, analysed by a combination of banding and Hoechst 33258 staining as outlined in Fig. 1. All human chromosomes found are listed above. Hybrid populations no. 1 and no. 3 were uncloned, while no. 2 and no. 4 were clonal. APRT was assayed as before[2,8]. Human α-globin mRNA was determined in induced hybrid MEL cells after 72 h of exposure to DMSO by RNA-cDNA hybridisation. Cytoplasmic extracts of those cells[7] were fractionated on columns of oligo (dT) as before[16]. Human α-globin mRNA, obtained from the reticulocytes of a nonthalassemic donor was purified from human β-globin mRNA first by electrophoresis on 5% polyacrylamide gels in 100% formamide[7,17]. Human globin cDNA was generated using the more rapidly migrating band (predominantly human α-globin mRNA) as a template for avian myeloblastosis reverse transcriptase as before[7]. Preparative hybridisation was used as before[7] to remove the 8–10% of this human α-globin cDNA that was complementary to non-α-globin mRNA. The human α-globin cDNA used was greater than 99% pure, and had a specific activity of 42,000 d.p.m. ng^{-1}. It migrated on 5% polyacrylamide gels as a single peak with a molecular weight of 230,000. Hybridisation was carried out as before[2,7] in 50% formamide and 0.5 M NaCl at 66°C for 90 h; each 2-μl reaction mixture contained 0.1 ng of cDNA in addition to the RNA from the hybrid cell. Hybrids were identified by resistance to S_1 nuclease[2,17]. Because the hybrid cells contained no non-α-globin genes and the hybridisation conditions prevented cross hybridisation of mouse globin mRNA with human globin cDNA (Fig. 3, ref. 7), the percentage hybridisation of the human α-globin cDNA was a measure of the amount of human α-globin mRNA present. To obtain the data shown in row H of Table 1, we added various amounts of poly ($A+$) RNA from hybrid cells or human reticulocytes to a fixed amount (0.1 ng) of human α-globin cDNA and incubated in 2-μl mixtures as described above. The percentage of human α-globin cDNA protected in each case was plotted against the ratio of poly ($A+$) RNA/human α-globin cDNA. The lowest ratio at which maximal protection of human α-globin cDNA was observed is given in row C. We then divided the ratios for each cell type given in row C into that for human reticulocytes (which was determined to be 3 in the same experiments), to generate an estimate of the relative level of human α-globin mRNA in each hybrid cell (shown in row D). We then conducted the same analysis using mouse reticulocytes and mouse globin cDNA to estimate the relative level of mouse mRNA in each hybrid cell, the results of which are shown in row E. The final levels of mouse globin mRNA in MEL cells vary as a function of induction and are not affected by the presence or absence of human chromosome 16 from either erythroid or non-erythroid donor cells; similar amounts of mouse α and β-globin chains were present in both these hybrid populations. We then divided the human α-globin mRNA levels (row D) by the mouse globin mRNA levels (row E) for each hybrid cell to normalise the human α-globin mRNA levels for the induction process variables. These normalised estimates of human α-globin mRNA generated for hybrid cells with human α-globin genes derived from donor cells of different types (given in row F) can then be compared to determine if the potential for human α-globin gene expression varies in different types of donor cells. These ratios following correction for the ratio of human α/mouse α-globin genes found in a hybrid MEL cell with a diploid complement of mouse chromosomes and a single human chromosome 16, are given in row H. ND, not done.

for full expression of human α-globin genes is chromosome 16.

In the study reported here, we isolated two different populations of hybrid cells (Table 1) derived by fusion of diploid APRT-deficient MEL cells with non-erythroid human haematopoietic cells in conditions outlined in Fig. 1. Neither human donor exhibited any abnormalities of globin gene expression in peripheral blood or marrow erythroid cells. Analysis of these hybrids by staining of metaphase spreads showed that an intact human chromosome 16 was retained in more than 80% of the cells studied while most of the other human chromosomes had been lost (as shown in Table 1 and Fig. 1). The presence of human APRT in these hybrid cells also confirmed the presence of human chromosome 16 (Table 1). As Fig. 2 and Table 1 (row I) show, there were no detectable human α-globin chains in either of the diploid MEL hybrid cells containing non-erythroid human α-globin genes, in spite of the presence of normal levels of mouse α- and β-globin chains.

Table 1 shows that the cloned hybrid MEL population no. 2 (devoid of human α-globin chains) and no. 4 (positive for human α-globin chains), both of which retained human α-globin genes from non-erythroid haematopoietic cells, differed only with respect to the presence of a diploid (no. 2) or a tetraploid (no. 4) complement of MEL chromosomes. We therefore compared the levels of human α-globin mRNA in these cells, by the methods outlined in Table 1. The relative level of human α-globin mRNA in the hybrid tetraploid MEL cells (no. 4) which contain non-erythroid human α-globin genes was 0.16 (Table 1, row H), eight times higher than that found in diploid MEL cells, suggesting that the MEL cell contained some factor or process which depended on the dosage of MEL chromosomes in the hybrid cell, and which resulted in higher steady state levels of human α-globin mRNA.

We next compared the relative levels of human α-globin mRNA in the DMSO-induced hybrid MEL cells no. 1 and no. 3,
Fig. 2 Pattern of globin chain synthesis in hybrid cells derived by fusion of non-erythroid human haematopoietic cells with diploid MEL cells. 5×10^6 cells from the hybrid cell population were collected after incubation for 5 d in 1.25% DMSO. Cells were then incubated for 6 h in 0.5 mCi of ^{3}H-leucine specific activity 50 mCi mmol^{-1}) dissolved in 25 ml of Ham's F-12 medium supplemented with 10% fetal calf serum. Fractionation of haemoglobin from other labelled cytoplasmic proteins was carried out on a 2-ml bed volume carboxymethyl cellulose column in 0.01 M phosphate buffer as discussed previously[4,7]. After extraction of haem, globin chains were fractionated in 8M urea–0.01 M phosphate at pH 6.9 on columns of carboxymethyl cellulose[15]. The solid circles define the elution profile of ^{3}H-leucine-globin chains from hybrid cell population no. 3, using a 2-ml fraction volume. Open circles define the elution profile of unlabelled globin chains added as markers.

both of which contained a diploid complement of MEL chromosomes as well as human α-globin genes from erythroid and non-erythroid haematopoietic cells respectively (Table 1). The ratio of human α-globin mRNA to mouse globin mRNA in hybrid population no. 1, the hybrid MEL cell which contains a single human chromosome 16 derived from erythroid donor cells, is 0.5, as shown in Table 1, row *F*. This ratio corresponds to an average of 3,000 copies of human α-globin mRNA per cell. In contrast, in the hybrid diploid MEL cell no. 3 which contained human α-globin genes on human chromosome 16 from non-erythroid haematopoietic cells, this ratio was only 0.02 (Table 1, row *F*), which is one-twenty-fifth (120 copies of human α-globin mRNA per cell) of that found when human α-globin genes come from an erythroid donor cell. Because hybrid no. 3 contains human chromosome 16 in the absence of all other human chromosomes, the data suggest that the mechanism which mediates the decreased potential of human α-globin genes in non-erythroid human haematopoietic donor cells is *cis*-effective and the pattern of expression of human α-globin genes in the hybrid diploid MEL cells is dependent on the differentiated state of the human donor. Whether these differences in human α-globin gene expression arise from differences in the DNA itself or from some other fixed chromosomal state which stabilises the expression of human α-globin genes cannot be concluded. The data suggest that at least one mechanism limiting expression of human α-globin genes in non-erythroid haematopoietic cells is *cis*-effective. Further studies in this system of the pattern of expression of human α-globin genes in mouse erythroleukaemia cells may help to clarify which regions of the gene or its neighbouring sequences are important in the regulation of globin gene expression in differentiated and undifferentiated cells.

Molecular consequences of deletion formation mediated by the transposon Tn9

Jeffrey H. Miller

Département de Biologie Moléculaire, Université de Genève, Genève, Switzerland

Insertion elements and transposons stimulate deletion formation, mediating the elimination of neighbouring host sequences at a high rate compared to the background of deletions occurring in their absence. The (non-lethal) deletions generated by a variety of transposable elements end at or near the terminus of the element[1] (for reviews see refs 2–4). The finding that transposable elements generate the repetition of a short segment of host DNA on either side of the integrated element[5,6] raises new questions about deletion formation at the sequence level. Do the deletions terminate at the precise endpoint of the element and remove the repeated sequence, or do they end within it or leave it intact? Is deletion formation linked to the transposition process? To study the above questions we have used the transposon Tn9, which carries the genetic determinants for chloramphenicol resistance flanked on either side by the insertion sequence IS1[7,8] (in the same orientation), and which like IS1 generates a nine base pair repeat upon integration[5,6,9]. Starting with a Tn9 integrated into the lacI gene of Escherichia coli, we examined deletions extending into the neighbouring lacZ and lacY genes. Sequence analysis, reported below, shows that after deletion formation the ends of the transposon remain intact, although one copy of the repeated 9 base pairs is removed by the deletion, fusing the end of Tn9 to host sequences several thousand base pairs away (in these cases). (Studies with Tn3[10], IS1[11] and IS2[12] are consistent with these results.) We also find that the Tn9-distal end of the deletions terminate preferentially within the same region of DNA in which Tn9 insertion points cluster, suggesting that the processes of deletion formation and transposition share a common pathway.

*Present address: Département de Biologie Moléculaire, Université de Genève, Sciences II, Genève, Switzerland.
Fig. 1 The map position of several Tn9 mediated deletions is shown. The starting strain, X7733, used for the generation of deletions has been described previously[23]. It carries Tn9 in the I gene of an F'lacproB episome and a galE⁻ mutation and a lacproB deletion on the chromosome. Although deletions can extend in either direction, only those causing the Z⁻ phenotype could be scored easily. The insertions lacI1::Tn9 and lacI2::Tn9 were used[9]. The map position of several Tn9-mediated deletions is shown. Cultures from single colonies were grown at 34 °C and streaked onto glucose minimal plates containing phenyl-β,D-galactoside[24] and the indicator dye 5-bromo-4-chloro-3-indoxyl-β,D-galactoside (Xgal)[25]. The starting strain cannot grow on this medium, although Z⁻ survivors form white colonies. From each culture four to eight colonies were picked and the Z⁻ mutations mapped against the Y⁻ point mutation YA7047 contained in strain CSH7[25]. Z⁻ colonies were present between 10⁻³ and 10⁻⁴ of the population, and ~15% of these gave Lac⁺ recombinants with CSH7. The respective mutations were mapped against other point mutations in Z (CSH1–6, CSH8–11)[25]. Only one deletion mutation derived from the same original culture was analysed. The Z⁻ point mutations shown in the above figure are in one of 27 intervals in the gene[25], indicated by the figures above the line. The deletion mutations ΔI-Z1 and ΔI-Z2 were chosen for subsequent sequence analysis.

The starting strains for this work carried a Tn9 insertion in the *lacI* gene of an F'*lacproB* episome (see legend to Fig. 1). Deletions can extend in either direction from the integrated element, although only those deletions which prevent Z expression can be easily detected in this system. We examined independently occurring Z⁻ derivatives from two different *lacI*::Tn9 insertions and mapped them against different point mutations in the *lac* region. Figure 1 shows the map position of several deletions detected in this manner.

The two deletions *lacI1*::Tn9ΔIZ1 and *lacI2*::Tn9ΔIZ2 were crossed genetically onto a plasmid derived from pMB9, pMC4[5], which contains *lacI* and most of *lacZ*, using techniques described previously[5,9]. Figure 2 depicts the restriction mapping and sequencing of the deletion endpoints. In each case, while the left juncture of Tn9 in the *I* gene is intact, the right end of Tn9 is now fused to sequences in the interior of *Z*. The element is now flanked by unrelated sequences of nine base pairs (Fig. 3). The exact ends of Tn9 are preserved. This includes 10 base pairs of the right arm and 50 base pairs of the left arm (as drawn in Figs 2 and 3) for Tn9 in ΔIZ2, and 65 base pairs of the right arm of Tn9 in ΔIZ1. Moreover, the *Hae*III restriction pattern is indistinguishable from the starting Tn9 in both cases.

As Fig. 3 shows, the derivatives of Tn9 resulting from deletions extending into the *Z* gene are no longer flanked by repeated sequences of nine base pairs. We determined the frequency of transposition of these Tn9 derivatives, as well as the starting Tn9 elements. Tables 1 and 2 show that the frequency of transposition is unaffected by the removal of the nine base pair repeat.

Table 1 Cointegrate formation mediated by Tn9 derivatives

pMC4 donor plasmid	Frequency of Camʳ colonies
lacI2::Tn9	4.7 ± 0.7 × 10⁻⁶
lacI2::TnΔIZ2	4.5 ± 0.5 × 10⁻⁶

An F factor carrying a non-transposable *kan'* marker (courtesy of Dr F. Heffron) was used to detect transposition of Tn9 from the pMC4 plasmid. The donor strain (R90C) background was recAΔ(lacproB) rif nalA. The F⁺ factor was transferred to a Strʳ recipient (Q90C) and the approximate frequency of transposition calculated by monitoring the proportion of Camʳ Kanʳ Strʳ colonies among the Kanʳ Strʳ colonies, averaged for 20 experiments in each case. (The error given in the Table represents the standard deviation.) Most of the colonies are Tetʳ, since the plasmid was transferred due to a presumed cointegrate intermediate in the transposition process, although 0.2% of the colonies were Tetˢ in each case. That the transfer of the plasmid is mediated by Tn9 was shown by the fact that almost no transfer (1.5 × 10⁻⁸) of Tetʳ is found when the pMC4 plasmid does not contain Tn9.

We examined the distribution of deletion endpoints in the *lac* region by characterising independently-occurring deletions generated by *lacI1*::Tn9. Only the Z⁻ phenotype was selected for initially, so any deletion extending into or past the Z promoter could be detected. We tested the *lacZ* mutations for recombination with the late Y⁻ amber mutation MAB19[13]. We subsequently mapped 65 of these deletions against a series of mutations in the Z gene and the Y gene. As Fig. 4 shows, most of the deletions (~80%) end within a region consisting of the very end of the Z gene and most of the Y gene, even though this region is only about one third of the size of the Z gene (assuming that Z and Y are not separated by a very large region). However, the deletion endpoints are distributed in many different places both in Z and Y.

We have examined the sequence alteration produced by two different Tn9-mediated deletions extending from the *lacI* gene into the *lacZ* gene. In both cases the deletions end at the exact
Fig. 2 Restriction mapping and sequencing deletion endpoints. *a*, The *Hind*II cuts in the *lacI* and Z genes. Distance between cuts is given in base pairs (bp). The single R1 cut in the region occurs 126 bp beyond the final *Hin* cut and 53 bp from the end of Z. The two Tn9-mediated deletions were crossed to pMC4, which contains this region up to the R1 cut. In a plasmid containing Tn9 in *I*, the 935 bp *Hin* fragment is replaced by a fragment 3,600 bp long (the 2,700 bp Tn9 has no *Hin* cuts). In plasmids carrying the deletions, the corresponding band is now 4,600 bp and comprises the first part of the 935 bp fragment of *I*, Tn9 and most of the 1,828 bp fragment of Z. The 789 and 618 bp *Hin* fragments are missing. A comparison of the restriction map of the 4,600 bp *Hin* fragment with the restriction map obtained from the wild-type *Hin* 1,828 bp fragment indicates that both deletions end within the first few hundred bases of the 1,828 bp fragment. Therefore, this wild-type region, in the centre of the Z gene (indicated by shading), was sequenced. *b*, Restriction map of the first 400 bp of the *Hin* 1,828 bp fragment. Distances are given in bp from the *Hin* cut. Fragments sequenced are indicated by arrows. *, Indicates ³²P. Sequencing was done by the method of Maxam and Gilbert[26]. Sequences on the upper strand were obtained by cutting a *Hin-Hpa* 238 bp fragment labelled with ³²P with *Hae*III, yielding the 155 bp fragment sequenced. A labelled *Hinf-Hinf* 112 bp fragment was recut with *Hpa* and the resulting 31 bp fragment was sequenced. A labelled *Hinf-Hinf* fragment approximately 800 bp long was recut with *Hpa* and a fragment approximately 70 bp long was sequenced. On the lower strand, labelled *Hind-Hinf* 207 bp and *Hinf-Hinf* 112 bp fragments were strand separated and sequenced. Also, the 207 bp fragment was recut with *Hae* and a 52 bp fragment was sequenced, and the 112 bp fragment was recut with *Hpa* and an 81 bp fragment was sequenced. *c*, Juncture of Tn9 and Z in *lacI2*::Tn9ΔIZ2. Starting with the 4,600 bp *Hin* fragment, a 365 bp *Hae* fragment extending from 210 bp inside Tn9 (IS1) to the *Hae* cut 155 bp from the *Hin* cut was isolated, labelled with ³²P, and recut with *Hinf*, yielding a 73 bp fragment which gave the juncture sequence on the lower strand. The upper strand of the same juncture was sequenced by labelling a 105 bp *Hinf* fragment extending from 10 bp inside IS1 to the *Hinf* cut 207 bp from the *Hin* cut, recutting with *Hae*, and sequencing 73 bp junction fragment. *d*, The sequence of the juncture of Tn9 and Z for *lacI1*::Tn9ΔIZ1 was obtained by isolating and labelling the 281 bp *Hae* fragment extending from the *Hae* cut 210 bp inside IS1 to the *Hae* cut 326 bp from the *Hin* cut. This fragment was recut with *Alu* and the 136 bp fragment giving the lower strand junction was sequenced. For both deletions the left juncture (in the *I* gene) was shown to remain intact by restriction mapping. In *lacI2*::Tn9ΔIZ2 the left juncture was also sequenced, using the *Hae-Hpa* junction fragment described[9] for *lacI2*::Tn9 and is identical to the juncture sequence reported there.

Fig. 3 *a*, The sequence of 360 base pairs starting from the *Hin*dII cut at the end of the 1,828 base pair fragment, as determined as shown in Fig. 2. Numbers refer to amino acids in the β-galactosidase sequence[27]. There are two minor differences from the reported protein sequence at positions 356 (Gln to Glu) and 412 (Asp to Asn). They are indicated by *. The position of the deletion endpoints of *lacI*::Tn9ΔIZI and *lacI2*::Tn9ΔIZ2 are shown; only the last 10 base pairs of Tn9 and the first few bases to which it is fused are shown. *b*, The nine base pair sequences now flanking Tn9 in the two deletions. Each Tn9 insertion was flanked by a direct repeat of the sequence shown on the left. After deletion formation it is flanked by unrelated sequences of 9 base pairs.

terminus of the element, eliminating one copy of the nine base pairs of *I* gene DNA which were repeated during the integration of Tn9. This result extends the genetic and biochemical work of other authors, which indicated that such deletions end within 50 base pairs or less of the respective terminus of the element[1-4]. Sequence studies with IS*1*, IS*2* and Tn*3*-mediated deletions are also consistent with the results reported here[10-12].

Tn9 derivatives which are no longer flanked by repeated sequences of 9 base pairs (Tables 1 and 2), transpose with normal frequencies (Tables 1 and 2), strengthening arguments that Tn9 transposition does not involve homologous pairing by this flanking sequence, but rather generates the repeated sequence during the process of insertion itself[9]. (Experiments with Tn*10* also argue that the flanking repeated sequences are not necessary for transposition[14].)

Genetic mapping of deletion endpoints in *Z* and *Y* shows that 80% of the endpoints fall within a region extending from the extreme distal end of *Z* to the end of *Y* (see Fig. 4), a region one third of the size of the remainder of *Z*; within this preferred region deletion endpoints occur at many different positions. Transpositions of Tn9 into *Z* and *Y* show a similar strong preference for *Y* and the end of *Z*, as ~98% of Tn9 transpositions into *Z* and *Y* occur in this region, and like the deletion endpoints the transpositions fall at many positions within it (ref. 9 and J.H.M, M.P.C. and D. Galas, unpublished results). Coincident specificities of both deletion endpoints and transposition integration points have also been reported for Tn*3*[15], Tn*1*[16] and Tn*10*[17], and argue for a common step in the mechanism of both events.

Table 2 Transposition of Tn9 derivatives to F⁺*kan*

Tn9 derivative (on chromosome of CSH51)	Frequency of Cam^r, Kan^r colonies (R90C background)
lacI1::Tn9	3.8 × 10⁻⁵
lacI1::Tn9ΔIZ1	4.0 × 10⁻⁵
lacI2::Tn9	3.8 × 10⁻⁵
lacI2::Tn9ΔIZ2	3.5 × 10⁻⁵

The Tn9 insertions were crossed by genetic recombination into the *lac* region of strain CSH51[24], which harbours a *lacproB* deletion and carries a φ80*dlac* prophage. (In order to determine that the recombinant carried the original insertion mutation, backcrosses were used, in which the insertion was re-crossed into an F*lacproB* episome and subsequently mapped and characterised.) After introduction of an F⁺*kan* factor these strains were used as donors in a cross against R90C (see legend to Table 1). The frequency of Cam^r, Kan^r, Rif^r colonies among the Kan^r, Rif^r colonies was determined in several experiments. The Cam^r, Kan^r colonies, when cured of the *kan^r* episome, also lost the Cam^r character, demonstrating that the Cam^r was carried by the F⁺ episome.

How does a transposable element cause a deletion in its vicinity? These sequence results show that, as in transposition, the exact end of the transposable element must be an active participant. Moreover, studies with bacteriophage Mu, a transposable element, show a structural requirement for both ends of Mu in deletion formation[18]; if one can generalise from this result then, presumably, both ends of Tn9 are involved in deletion formation. These findings and the coincident specificity of deletion endpoints and transposition integration sites indicate a close relationship between transposition and deletion formation. Models giving a specific mechanism linking deletion formation to transposition have been proposed[19,20]. Shapiro[20] has outlined a mechanism for transposition in which a copy of the transposable element is replicated into the target site. When this mechanism is applied to transposition to a nearby site within the same replicon, in one orientation a deletion will result generating a fusion of the end of the transposable element to a new sequence, having the structure that we found, plus another copy of the transposable element fused to the deleted material. In the opposite orientation a second copy of the transposable element occurs in inverted orientation, along with inversion of the intervening material. (We have not examined inversions in our study of *Z⁻* mutations.) Thus, a deletion may be the result of a transposition event, when the target for transposition is an adjacent region on the same chromosome. In this regard it would be interesting to examine the effect on deletion formation of host mutations affecting transposition frequencies, and vice
Fig. 4 The distribution of deletion endpoints generated by Tn9. The Tn9 insertion *lacI1*::Tn9 was used to generated deletions in *Z* and *Y*. The top part of the figure shows that 10 of 65 deletions terminate within the major portion of *Z*, whereas 55 deletions end in *Y* or at the very end of *Z*. As can be seen in the lower part of the diagram, many different endpoints are involved. The deletions were mapped against point mutations in *Z*[25] and *Y*[13] whose positions are indicated by the vertical lines along the lower part of the figure. The values in parentheses indicate the number of deletions with endpoints in this interval. Experimental details were the same as those given in the legend to Fig. 1, except that 32 °C was used, and the late *Y⁻* mutation *MAB19*[13] mapping at the far end of the *Y* gene was used for initial screening. Approximately 25% of the *Z⁻* mutations were deletions ending before *MAB19*.

versa. One mutation that apparently decreases the rate of IS*1*-mediated deletions has been reported[21].

The structure of *int*-mediated deletions from the *att* site of phage λ is analogous to the structure of deletions mediated by transposable elements and has been interpreted in a similar fashion; that is, as integration events into adjacent regions of the λ chromosome instead of into the normal bacterial *att* site[22].

Migration of capillary endothelial cells is stimulated by tumour-derived factors

Bruce R. Zetter

Department of Surgery, Children's Hospital Medical Center and the Department of Microbiology and Molecular Genetics, Harvard Medical School, Boston, Massachusetts 02115

Angiogenesis, the growth of new blood vessels, occurs normally during osteogenesis, luteinisation and the development of the embryo, and in pathological states such as chronic inflammation, certain immune reactions and neoplasia[1]. Furthermore, solid tumours have been reported to secrete a diffusible factor which promotes the directional growth of new capillaries towards a growing tumour[2]. Two events required for the formation of a new capillary in response to an angiogenesis factor *in vivo* are the migration and subsequent proliferation of capillary endo- thelial cells[3]. Progress in purifying angiogenesis factors and studying their action has been hindered, however, by the lack of quantitative *in vitro* assays for capillary cell migration and proliferation. Recently, we have been able to isolate clonal cell lines of bovine capillary endothelial cells that can be maintained in long-term culture using tumour-conditioned growth medium[4]. I now report a quantitative *in vitro* assay for endo- thelial cell migration based on the phagokinetic track assay of Albrecht-Buehler[5]. The evidence presented here demonstrates that tumour-derived factors stimulate the migration of capillary endothelial cells whereas the same factors have no effect on the migration of aortic endothelial cells.

In the elegant system devised by Albrecht-Buehler to analyse the movement of cultured cells, the cells are first plated onto glass coverslips that have been previously coated with gold particles[5]. The cells ingest the gold and, as they move, leave bare areas or tracks that serve as a record of their movement. Figure 1 demonstrates the phagokinetic tracks made by bovine capillary endothelial (BCE) cells during an 18-h period. In normal growth medium containing 10% calf serum, little phagokinetic move- ment takes place (Fig. 1*a*). In contrast, when the assay is carried out in medium conditioned by mouse sarcoma 180 cells, phagokinetic movement increases and the size of the tracks is significantly larger than for cells incubated in non-conditioned medium (Fig. 1*b*).
Fig. 1 Tumour-stimulated migration of bovine capillary endothelial cells. Bovine capillary endothelial cells (3,000) were seeded on gold-coated 22 × 22 mm glass coverslips prepared according to the method of Albrecht- Buehler. The cultures were incubated at 37 °C in Dulbecco's modified Eagle's medium containing 10% calf serum (DME-CS) until the cells had attached to the coverslips (~4 h). The coverslips were then transferred to 35-mm culture dishes containing either DME–CS alone (*a*) or mixed 1:1 with sarcoma-conditioned medium prepared as described in ref. 4 (*b*). After an additional 18 h, the medium was removed and replaced with 2.5 ml of 10% buffered formalin phosphate (Fisher Scientific) to terminate the experiment. The phagokinetic tracks were observed under incident light with a Nikon MS inverted microscope and photographed using a Wild MKa4 photoautomat camera. ×20.

It has been noted that an increased rate of cell movement will be reflected by an increased phagokinetic track size[6], but there have previously been no reports of a quantitative migration assay based on this technique. In the experiments reported here, the precise dimensions of endothelial cell phagokinetic tracks were measured with the aid of a MOP-3 digital image analyser (Carl Zeiss) as described in Fig. 2 legend. For each experimental point, the outlines of 100 tracks were traced and analysed to determine the perimeter length, maximum diameter and area. Because an increase in cell locomotion does not always correlate with an increase in directionality of movement[7], the pattern of the tracks is highly irregular and therefore an increase in phagokinetic movement can best be detected as an increase in the mean area of the tracks rather than by their absolute lengths. Therefore, in all figures, migration is expressed in units of area of the phagokinetic tracks (μm^2).

Quantitative measurement of BCE cell phagokinetic tracks reveals that there is a linear increase in track size as the concentration of tumour-conditioned medium is increased between 0 and 100% (Fig. 2). Whereas the capillary endothelial cells move slowly in the absence of tumour-conditioned medium and rapidly in its presence, aortic endothelial cells move rapidly regardless of the presence or absence of tumour-conditioned medium (Fig. 2). These results are consistent with our previously published observations on endothelial cell proliferation. Capil- lary endothelial cells grew slowly in normal growth medium but rapidly in tumour-conditioned medium whereas aortic endo- thelial cells grew rapidly in either[4].

To determine whether medium conditioned by other cell
Fig. 2 Effect of sarcoma-conditioned medium on migration of bovine capillary and aortic endothelial cells. Bovine capillary endothelial cells (3,000) (●) or bovine aortic endothelial cells (□) were seeded on gold-coated coverslips as described in Fig. 1 legend and incubated for 18 h in DME-CS supplemented with the indicated concentration of sarcoma-conditioned medium. At the end of the experiment, the images of the phagokinetic tracks were transferred from the inverted microscope (×4 objective) to the screen of a Setchell–Carson 10M915 television by means of an RCA TC1005 video camera. The images were then traced from the television screen onto sheets of transparent plastic which were subsequently placed onto the magnetic tablet of a Zeiss MOP-3 digital image analyser. The tracings of the phagokinetic tracks were then retraced using the magnetic stylus of the MOP-3 and automatically processed for dimensions of area (shown above) as well as maximum diameter and length of perimeter. To eliminate consideration of cell division or cell collisions, only tracks formed by a single cell were analysed. Each point represents the mean area of 100 samples ± s.e.m. The inset shows the phagokinetic tracks of capillary (*a*) and aortic (*b*) endothelial cells in non-conditioned medium.

types might also stimulate endothelial cell migration, harvest fluid was collected from rapidly growing cultures of bovine aortic endothelial cells, bovine smooth muscle cells, BCE cells and mouse sarcoma 180 cells. When these media were tested for their ability to stimulate BCE cell phagokinetic movement (Fig. 3), the smooth muscle and aortic endothelial cell-conditioned media were completely inactive. Medium conditioned by the capillary endothelial cells themselves induced a 20% increase in the size of the phagokinetic tracks whereas the sarcoma cell-conditioned medium brought about a 90% increase. Once again, aortic endothelial cell tracks were large in the absence of any conditioning factors. None of the conditioned media caused an increase in the size of the aortic cell tracks to greater than 10% beyond control values (Fig. 3). In a second series of experiments, conditioned media from several other normal cell types had no effect on the migration of either capillary or aortic endothelial cells. The cell types tested included Swiss mouse 3T3 cells, F2408 Fisher rat embryo fibroblasts, early-passage human

Table 1 Growth of capillary endothelial cells in medium conditioned by sarcoma 180 cells or aortic endothelial cells

Growth medium	Cell no. after 5 days
Non-conditioned medium (10% calf serum)	2.14×10^4
Sarcoma 180-conditioned medium	8.4×10^4
Aortic endothelial cell-conditioned medium	6.8×10^4

10^4 cells were seeded in gelatin-coated 16-mm tissue culture wells containing 1 ml of non-conditioned medium. After 18 h to allow plating, the medium was aspirated and replaced with test medium prepared as described in Fig. 3 legend. All test media contained a final concentration of 10% calf serum. Fresh test medium was added on day 3. On day 5, the cells were removed from the wells with 0.25% trypsin and counted with a Coulter Model Zf particle counter.

diploid skin fibroblasts, MDCK canine kidney epithelial cells and primary C57 mouse bladder epithelial cells. In contrast to these normal cells, medium conditioned by benzpyrene-transformed C57 mouse bladder epithelial cells had significant migration-stimulating activity (data not shown).

It could be argued that if migration were an obligatory response to any growth stimulus, the migration assay would simply be an indirect measure of mitogenic activity. However, aortic endothelial cell-conditioned medium stimulates the growth of BCE cells to a level nearly equivalent to the sarcoma conditioned medium (Table 1), but has no effect on the BCE cell migration as shown in Fig. 3. This indicates that BCE cell growth and migration are independent events and might therefore be mediated by separate factors.

In a preliminary attempt to determine whether a quantitative assay could be devised to detect angiogenesis factors based on their ability to stimulate endothelial cell movement, increasing concentrations of an extract of human hepatoma cells were tested for their ability to increase the size of BCE cell phagokinetic tracks. This same extract shows angiogenic activity in the rabbit cornea and the chick chorioallantoic membrane (data not shown). Figure 4 shows that an increase in track size can be detected with 0.1 μg ml^{-1} and reaches a peak at 100 μg ml^{-1}. As neovascularisation is a complex phenomenon involving basement membrane hydrolysis, cell proliferation, cell junction formation and lumen formation in addition to cell migration[3], it is unlikely that any single *in vitro* assay could totally replace the *in vivo* bioassays that have been developed to study angiogenesis[1]. Nevertheless, the migration assay described here should provide a sensitive, rapid (18 h), quantitative assay for one critical component of angiogenesis.

The quantitative assay described above has already proved useful in demonstrating the effect of tumour-derived factors on
Fig. 3 Effect of conditioned medium from several different cell lines on the migration of bovine capillary and aortic endothelial cells. Bovine capillary endothelial cells (3,000) (left panel) or bovine aortic endothelial cells (right panel) were seeded on gold-coated coverslips as described in Fig. 1 legend and allowed to migrate for 18 h at 37 °C in DME-CS that had been mixed 1:1 with conditioned medium prepared by 48 h incubation with subconfluent cultures (6.6 × 10^4 cells cm^{-2}) of bovine aortic smooth muscle cells (SMC), bovine aortic endothelial cells (BAE), bovine capillary endothelial cells (BCE) and mouse sarcoma 180 cells (MS). For each sample, 100 phagokinetic tracks were traced from the television screen and retraced on the magnetic tablet of the Zeiss MOP-3 image analyser for determination of mean track area ± s.e.m.

Fig. 4 Effect of human tumour extracts on capillary endothelial cell migration. Human hepatoma cell extracts provided by Dr B. Wildi were prepared by incubating suspensions of cultured hepatoma cells (5×10^7 cells ml^{-1}) in phosphate-buffered saline for 4 h at 4 °C. The cells were removed by centrifugation and the resulting supernatant was concentrated and diluted in phosphate buffer (0.1 M NaH$_2$PO$_4$–0.02% NaN$_3$) four times to remove the saline. The final concentrate was applied to a CM-Sephadex C-50 column equilibrated with the 0.1 M phosphate buffer. The material that eluted with the starting buffer was collected, pooled, dialysed and lyophilised. Increasing concentrations of this material were added to 35-mm culture dishes containing 2 ml DME-CS. Gold-coated coverslips onto which 3,000 bovine capillary endothelial cells had been plated were transferred into these culture dishes and incubated 18 h at 37 °C. Areas of the phagokinetic tracks were determined as described in Fig. 2 legend. Each point represents the mean area of 100 samples ±s.e.m.

capillary cell migration and in so doing has pointed out a fundamental difference between capillary endothelial cells and endothelial cells from larger vessels. Furthermore, it may lead to a new understanding of certain biological agents such as interferon, which we have recently found can act as a reversible inhibitor of cell migration[8]. The application of this method is not limited to endothelial cells. Phagokinesis can be studied with virtually any motile cell that adheres to a substratum[5,6]. Thus, many cellular movements that were previously amenable to study only by time-lapse microcinematography may now be quantified by measurement of cell tracks. Possible uses could include the study of migration of neural cells, leukocytes and embryonic cells, the migration patterns of invasive and metastatic cells and the screening of cancer chemotherapeutic agents for anti-migratory activity.

Histone H1⁰ accumulates in growth-inhibited cultured cells

John Pehrson & R. David Cole

Department of Biochemistry, University of California, Berkeley, California 94720

The H1 class of histones contains several molecular species, even within a single organism [1]. The combination of these subfractions varies according to the state of terminal differentiation[2,3], embryonic development[4] and hormonal induction[5]. One of the subfractions, H1⁰, occurs at levels that are inversely correlated with the rate of cell division in mammalian tissues[6]. Although H1⁰ might be functionally or even structurally distinct from the usual H1 histone, Panyim and Chalkley[6] established that its size and amino acid composition resembled other H1 histones. The quantitative studies of its relationship to mitotic index were greatly extended by Marks *et al.*[7], and others[8-12] have measured H1⁰ contents during processes such as tissue regeneration and selective tissue destruction. All these observations were consistent with the notion that histone H1⁰ suppresses gene replication. One limitation in these demonstrations of the inverse correlation between H1⁰ and cell division is that there are many variable parameters, other than mitotic index, when comparing one tissue to another. This problem is largely overcome by comparing regenerating tissues to their normal counterparts[8-11]. In the latter situation, it is possible that cell types which always have low H1⁰ contents are preferentially replaced early in the regeneration process, while different cell types with high H1⁰ levels build up in the tissue later. If it could be demonstrated that H1⁰ accumulated along with the arrest of cell division in a single cell type, these ambiguities would be removed. We report here such a demonstration using cultured cells.

Comparisons were made between the H1⁰ content of rapidly growing HeLa cells and that of cells whose growth had been inhibited by high cell density (after 10 days culture on a plate). Another comparison was made between H1⁰ levels in rapidly growing mouse neuroblastoma cells, and the same cells whose growth was inhibited by serum deprivation (4 days without serum). In both cases there were substantially higher amounts of H1⁰ (relative to other H1 histone) in the more slowly dividing cells. H1 histones were selectively extracted using perchloric acid (PCA) and submitted to polyacrylamide gel electrophoresis (Fig. 1). An electrophoretic band, assumed to be H1⁰ because of its mobility[6], was clearly more pronounced in preparations from growth-inhibited HeLa cells, than in those from rapidly growing cells, and it was clearly present in higher amounts in extracts of serum-deprived neuroblastoma cells than it was in their rapidly

Table 1 Levels of histone H1⁰ in rapidly growing and growth-inhibited cells

Cell	Growth state	Relative H1⁰ content
Neuroblastoma	rapid growth	0.08 ± 0.01
	serum deprived	0.30 ± 0.06
HeLa	rapid growth	0.05 ± 0.01
	density inhibited	0.20 ± 0.02

Polyacrylamide gels were stained in aqueous 0.03% (w/v) Coomassie blue R-250, 24% (v/v) isopropanol, 10% (v/v) acetic acid; and destained in 0.003% Coomassie blue, 10% isopropanol, 10% acetic acid followed by washing in 10% acetic acid. The gels were scanned at 610 nm. H1⁰ content is given as the ratio of H1⁰ to the ordinary H1 which is essentially constant in all chromatin[15]. Each ratio is the average of 5 to 14 observations with the standard deviations shown.
Fig. 1 Gel electrophoresis of perchloric acid (PCA) extracts of rapidly dividing and growth-inhibited cells. HeLa cells were grown on tissue culture flasks at 37 °C, 5% CO_2, in Dulbecco's modified Eagles medium (DMEM) with 5% calf serum. Mouse neuroblastoma cells N-115 (from Marc Kirschner) were grown on flasks at 37 °C, 10% CO_2, in DMEM supplemented with glutamine (2 mmol per 1 of DME), and 10% fetal calf serum except as indicated. Whole cells were extracted twice with 0.74 M PCA: the extracts were combined and trichloroacetic acid was added to 20% to precipitate the proteins. The precipitate was washed twice with ethanol, dried and electrophoresed in polyacrylamide, acetic acid, urea gels according to Panyim and Chalkley[16], except that the acrylamide was reduced to 7.5%. *a*, High density HeLa; *b*, rapidly growing HeLa; *c*, serum-deprived mouse neuroblastoma; *d*, rapidly growing mouse neuroblastoma.

growing counterparts. A quantitative analysis of several such experiments is presented in Table 1. The increase of H1⁰ in both types of cells was about three- to fourfold when cell division was inhibited.

To prove the identity of the putative H1⁰, we purified it from PCA extracts of serum-deprived mouse neuroblastoma cells and submitted it to amino acid analysis. For this purpose we used chromatography on Bio-gel P100 (ref. 13), which was more rapid than the previously used Biorex 70 chromatography[6]. A representative chromatogram is shown in Fig. 2 along with electrophoretic analyses of the two peaks. The amino acid composition of the purified H1⁰ listed in Table 2 is like that of the H1⁰ reported by Panyim and Chalkley[6].

Table 2 Amino acid composition of H1⁰

Amino acid	Mol %
Asp	3.9
Thr	5.4
Ser	9.1
Glu	6.1
Pro	8.2
Gly	4.3
Ala	16.6
Val	6.5
Met	0.7
Ile	2.4
Leu	2.1
Tyr	0.8
Phe	0.9
Lys	28.8
His	0.5
Arg	3.3

H1⁰ was hydrolysed in 6M HCl, 0.1% phenol for 20 h at 110°C. The figures are averages from two determinations using a Beckman amino acid analyser.

These results make it clear that histone H1⁰ content is not just a static characteristic of certain cells that become enriched in mitotically inactive tissues, but that H1⁰ levels are associated with a functional change in individual cells. Moreover, they suggest the possibility that H1⁰ is synthesised at times other than the S phase. In this regard it might be asked if H1⁰ ought to be compared to histone H5, whose synthesis is also not dependent on S phase[14]. The fact that both of these histones suppress chromatin activity adds interest to the comparison of H1⁰ and H5, metabolically, structurally and functionally. Such studies are under way.

Fig. 2 Bio-Gel P-100 chromatography of PCA extracts. The 0.74 M PCA extract of serum-deprived mouse neuroblastoma cells was dissolved in 8 M urea, 0.01 M HCl and applied to a 2 × 150 cm Bio-Gel P-100 column equilibrated in 0.01 M HCl. The column was eluted with 0.01 M HCl at a flow rate of 6 ml h⁻¹. Fractions (1.2 ml) were collected, peaks were pooled, lyophilised and subjected to polyacrylamide electrophoresis, as shown inset. The left hand lane represents the earlier chromatographic peak, while the right hand lane corresponds to the other peak.

Continuous synthesis of long DNA chains by chick embryo DNA polymerase γ

Masamitsu Yamaguchi*, Akio Matsukage†
& Taijo Takahashi

Laboratory of Biochemistry, Aichi Cancer Center Research Institute, Chikusa-ku, Nagoya 464, Japan

There is evidence for at least two mechanisms of DNA replication in eukaryotic cells. One is nuclear DNA replication in which DNA strands are synthesised in relatively short pieces (4–5S) that are later elongated and joined together[1–6]. These short DNA intermediates are also observed in the replication of viral DNA such as polyoma virus[7,8] and simian virus (SV40)[11,12], but not in adenovirus DNA[13,19] and mitochondrial DNA[15], where longer DNA chains are synthesised continuously. Studies of the subcellular localisation and the inhibitors of DNA polymerases[16,17] suggest that DNA polymerase α, β and γ are involved in nuclear DNA replication, DNA repair and mitochondrial DNA replication, respectively. And it is suggested that DNA polymerase α and γ are involved in the replication of SV40 DNA[18] and adenovirus DNA[19], respectively. Does the difference between the two types of replication depend on the difference in the reaction property of DNA polymerases α and γ? DNA polymerase α from human KB cells incorporated about 11 nucleotides per binding event[20]. Using mouse enzymes we found that one DNA polymerase β molecule polymerises dTMP on the multiple oligo(dT) primers with poly(rA) templates in a highly discontinuous fashion, while DNA polymerase γ may synthesise rather long poly(dT) chains in a one enzyme–one product fashion. We report here that using nearly homogeneous chick embryo DNA polymerase γ, the results clearly indicating that one DNA polymerase γ molecule synthesises one long DNA in a highly progressive fashion.

DNA polymerase γ was purified from an extract of 11-day chick embryos by phosphocellulose column chromatography, ammonium sulphate fractionation, gel filtration on Sephadex G-200, hydroxylapatite column chromatography and native DNA–cellulose column chromatography. The final preparation has a specific activity of 570,000 units (nmol ³H-dTMP incorporated per h at 37 °C) per mg protein with poly(rA) · oligo(dT) as a template · primer. A typical result of SDS-polyacrylamide gel electrophoresis is shown in Fig. 1. The major polypeptide which accounts for 86% of total protein is the polypeptide with a molecular weight (MW) of 47,000. This was the only polypeptide whose amount varied in proportion with the DNA polymerase activity during DNA–cellulose column chromatography, indicating that the 47,000-MW polypeptide was the only component of DNA polymerase γ. Purified DNA polymerase γ (149.4 U) was applied to SDS-polyacrylamide gel and the amount of the 47,000-MW polypeptide was determined as 0.224 μg (Fig. 1). Therefore, the specific activity with respect to the 47,000-MW polypeptide is 660,000 U per mg protein. The result of gel filtration and the sedimentation coefficient (7.5S in the presence of 1 M KCl and 0.5% Triton X-100) indicate that the molecular weight of this enzyme is about 180,000 (data not shown), assuming that this enzyme is spherical (as our preliminary electron-microscopic observation suggests). Therefore, it is comprised of four identical 47,000-MW polypeptides. From the specific activity and the molecular weight of this enzyme, the turnover number is calculated as 1,980 nucleotides per min per enzyme molecule.

The size of poly(dT) products synthesised by the highly purified chick embryo DNA polymerase γ on poly(rA) · oligo(dT) was analysed by alkaline sucrose gradient centrifugation. Polymerisation of ³H-dTMP continued almost linearly for at least 2 h (Fig. 3a). The sizes of products synthesised in the reaction for 0.4, 0.9, 1.5, 2 and 3 min were 7.0S, 11.9S, 13.0S and 13.9S, respectively (Fig. 2). After 3 min, the rate of chain elongation levelled off and the size of products synthesised in a reaction lasting 10 min or longer was always 14.6S. Molecular weights of the products were calculated from sedimentation coefficients according to Abelson and Thomas[22], and represented in nucleotide number (Fig. 3b). The initial chain elongation rate was about 1,900 nucleotides per min. The final length (average about 4,100 nucleotides) was reached at about 4 min—after that the size did not change but the number of products at the final length increased. Further studies are necessary to clarify how the final length is determined.

The coincidence of turnover number and DNA chain elongation rate indicates that one DNA polymerase γ molecule completes synthesis of one long poly(dT) chain before it starts with the other primer. The number of the products (equal to the number of dTMP molecules incorporated per average number of nucleotides per product) per enzyme molecule (number of enzyme molecules was calculated from the specific activity of the 'pure' enzyme, the molecular weight and the amount of enzyme

Fig. 1 SDS-polyacrylamide gel electrophoresis of the purified DNA polymerase γ. The detailed procedure for the purification of DNA polymerase γ from chick embryo will be published elsewhere. Extract was made by homogenisation, ultrasonication and centrifugation in the presence of 0.5 M KCl and 0.5% Triton X-100. Purification steps were: phosphocellulose column chromatography with stepwise elution; ammonium sulphate fractionation (0–55% saturation); a second phosphocellulose column chromatography with the elution in a linear salt gradient; gel filtration on a Sephadex G-200 column, hydroxylapatite column chromatography and native DNA–cellulose column chromatography. The preparation in the most purified fraction of DNA–cellulose column chromatography was used as the electrophoresis sample. DNA polymerase activity was determined in Fig. 2 legend DNA polymerase γ (149.4 units) eluted from a native-DNA cellulose column, which has a high specific activity of 570,000 U per mg protein, was precipitated with 15% trichloroacetic acid, redissolved in 20 μl sample buffer containing 0.0625 M Tris-HCl (pH 6.8)/2% SDS/10% (v/v) glycerol/5% (v/v) 2-mercaptoethanol/0.001% bromphenol blue, then electrophoresed essentially as described by Laemmli[25], in which 10% acrylamide slab gel of 1 mm thickness with 5% condensation gel was used. After electrophoresis (8 h at 60 V), the gel was fixed and stained with 0.1% Coomassie brilliant blue in 10% acetic acid/25% isopropanol and was destained with 10% acetic acid/10% isopropanol. The gel was photographed (bottom) and scanned at 600 nm by a Fujiox scanning densitometer (top). The molecular weight of the polypeptide band was estimated by comparison of its mobility to those of marker proteins: *Escherichia coli* RNA polymerase containing subunits of β' (MW160,000), β (MW150,000), σ (MW90,000), and α (MW40,000); bovine serum albumin (MW68,000); ovalbumin (MW45,000); bovine α-chymotrypsinogen (MW23,000). The protein amount in the gel was determined by comparing with the intensity of stained standard proteins of the known variable amounts (0.1–2 μg). Standard proteins were electrophoresed and stained in the same conditions as DNA polymerase γ. The average value of dye-intensity of three proteins; bovine serum albumin, ovalbumin and α-chymotrypsinogen, was used as the calibration standard.

used) was one for the initial 3 min of the reaction, and then increased in proportion to reaction time (Fig. 3c and inset). One enzyme molecule synthesised 35 products in 120 min, indicating that the average time required to complete one product is 3.4 min, agreeing very well with the time of termination of chain elongation (Fig. 3b). Thus, the mechanism of DNA chain elongation of chick embryo DNA polymerase γ is highly progressive.

In contrast, a mouse DNA polymerase β molecule synthesises poly(dT) chains on many primers in a highly discontinuous way[21]. The number of products per DNA polymerase β molecule was always about 30 for the long reaction time, and the average size of all products increased slowly and consistently for at least 30 min[21]. The processive nature of DNA polymerase α is not so great as that of DNA polymerase γ (refs 20, 23). Furthermore, our unpublished data indicate that the DNA products synthesised by DNA polymerase α are short (about 3-4S), using mouse enzyme and single-stranded calf thymus DNA-3'-(dT)_n with oligo (rA) as a template · primer. Thus, the reaction properties of DNA polymerases α, β and γ are different from each other.

The behaviour of DNA polymerase γ in DNA chain elongation makes it suitable for the replication of mitochondrial DNA and adenovirus DNA which are synthesised continuously
Fig. 2 Alkaline sucrose gradient centrifugation of poly(dT) products synthesised by DNA polymerase γ. The products were synthesised by highly purified DNA polymerase γ in optimal conditions. Reaction mixtures were incubated at 37 °C for 0.4, 0.9, 1.5, 2, 3, 10, 35 and 120 min in a final volume of 100 μl contained the following components: 50 mM Tris-HCl (pH 8.5), 0.5 mM MnCl₂, 1 mM dithiothreitol, 110 mM KCl, 20 mM potassium phosphate, 400 μg per ml bovine serum albumin, 14% glycerol, 80 μg per ml (rA)_m, 16 μg per ml (dT)_{12-18}, 12.7 μM ³H-dTTP (1837 c.p.m. pmol⁻¹), and 0.65 U DNA polymerase γ. After incubation, a 5-μl portion of each reaction was withdrawn to measure the amount of ³H-dTMP incorporated into poly(dT) as described previously[21]. The other portion (95 μl) was mixed with an equal volume of a 2×denaturing solution containing 2 M NaCl, 0.6 M NaOH, 1.5% Sarcosyl and 30 mM EDTA, then incubated at 37 °C for 20 min. 100 μl aliquots of the resulting solutions were layered over 4.8 ml 5-20% sucrose gradients made in the solution containing 1 M NaCl, 0.3 M NaOH and 5 mM EDTA, and then centrifugation was carried out for 15 h at 38,000 r.p.m. at 5 °C in an RPS 42T2 rotor of a Hitachi ultracentrifuge. The gradient was fractionated into 27 fractions from the bottom and a 100-μl portion was placed on a DEAE-cellulose paper disk and washed as described elsewhere[21]. Radioactivity in poly(dT) retained to the disk was measured using a Beckman liquid scintillation counter. Authentic poly(dA) (8.5S) was centrifuged in an accompanying tube as a sedimentation marker, and the position was determined by measuring the absorbance at 260 nm.
Fig. 3 The time course of incorporation of ³H-dTMP into poly(dT) (a), elongation of poly(dT) chains (b) and the number of products per DNA polymerase γ molecule (c). Incorporation of ³H-dTMP was measured as described in Fig. 2 legend. The chain length of poly(dT) products was calculated from the sedimentation coefficients as described previously[21] and represented as the number of dTMP residues. The mole number of products was calculated by dividing the mole number of incorporated ³H-dTMP by the chain length. The mole number of DNA polymerase γ was calculated from the unit of enzyme used, the molecular weight and the specific activity of the homogenous enzyme as described in the text.

without short intermediates. This is in good agreement with observations[13,24] that have suggested that DNA polymerase γ is involved in the replication of mitochondrial and adenovirus DNA.

We thank Miss M. Nishizawa for assistance. This work was supported in part by a Grant-in-Aid for Cancer Research from the Ministry of Education, Science and Culture, Japan and by a grant from the Research Foundation for Cancer and Cardiovascular Diseases, Osaka, Japan.

Conservation of segmental variants of satellite DNA of *Mus musculus* in a related species: *Mus spretus*

S. D. M. Brown & G. A. Dover

Department of Genetics, University of Cambridge, Downing Street, Cambridge CB2 3EH, UK

Fig. 1 Analytical UV absorbance profiles of Hoechst 33258–CsCl gradients after sedimentation to equilibrium for 18 h at 44,000 r.p.m. at 25 °C on a Centriscan 75 analytical centrifuge: *a*, *Mus musculus*; *b*, *Mus spretus*. 10 μg of DNA were bound to 10 μg Hoechst 33258 in the presence of 1% Sarkosyl[21]. CsCl was added to an initial density of 1.64 g cm⁻³. Arrow indicates *M. musculus* satellite band. H and L indicate heavy and light sides of the gradient respectively.

There has been much recent discussion on the biological function of the highly-repetitive DNAs (satellite DNAs) of higher organisms[1–9], that have several curious features of sequence organization. First, some satellite sequences show a high degree of conservation between related species[10–15]. Second, there is independent evolution of 'type B' segments (sequence variants) within a block of tandem repeats[16]. The majority of the *Mus musculus* satellite DNA can be cut to produce a type A pattern with either *Eco*RII or *Ava*II (ref. 8). However, digestion of *M. musculus* satellite with other enzymes produces a limit series of fragments from only part of the total satellite (type B segment)[16]. To understand the significance of the segmental sequence variants, it is necessary to characterize their distribution between individual chromosomes of a genome[18] and between closely related genomes. We report here the distribution of type A and B patterns in the two closely related species, *Mus musculus* and *Mus spretus*[19,20]. The data show that the genome of *M. spretus* contains homologous sequences that are organized into the same type B segments as *M. musculus*, except for one type B segment that is underrepresented in *M. spretus*. From a knowledge of the genetic distance and hybrid fertility between these species[19,20], we are able to exclude one of the proposed biological roles for these particular genomic components.

Analytical equilibrium sedimentation in neutral CsCl of total DNA of *M. spretus* that is bound to the dye Hoechst 33258 does not reveal a satellite DNA component (Fig. 1*b*) equivalent to that resolved from the total DNA of *M. musculus* sedimented in the same conditions (Fig. 1*a*). Hoechst 33258–CsCl density gradient centrifugation is a method that is particularly sensitive for the resolution of small amounts of AT-rich satellites[17,21].

To detect any '*musculus*' type A or B patterns in *M. spretus* it is necessary to use a sample of pure total satellite DNA of *M. musculus*, that contains all sequence variants, in 'Southern' hybridizations[23] against *M. spretus* DNA after digestion with type A or B enzymes. In order to obtain a probe of high purity, total *musculus* DNA was resolved into satellite and main-band components after repeated fractionation in Hoechst 33258–CsCl gradients. The final purity of the satellite was monitored by restriction with a type A enzyme to produce the expected complete pattern of fragments (Fig. 2*a*) and by analytical centrifugation. On this basis we are confident that the *musculus*

type A and type B variants detected by the probe in *M. spretus* are unlikely to be due to the presence of other contaminating components. A type B pattern of the probe is shown in Fig. 2*b*.

The majority of the *M. spretus* sequences that are homologous to the *M. musculus* satellite were susceptible to *Ava*II in that little homologous material remained at the origin (Fig. 3*a*). The amount of homologous '*musculus*' sequences in *M. spretus* has been estimated as ~1% (at this stringency of hybridization) both
Fig. 2 Type A and type B patterns in *M. musculus*. Ethidium bromide stained agarose gel after *Ava*II digestion (*a*) and *Hinf* digestion (*b*) of *M. musculus* satellite DNA. Arrows indicate an ascending series of multimers based on a monomer length of approximately 240 base pairs (lowest arrow). O indicates undigested material left near the track origin. Purified satellite was prepared as described previously[17] and 5 μg digested for 2 h with 2 units *Ava*II in 80 mM tris-HCl (pH 7.4), 10 mM MgCl₂, 30 mM NaCl at 37 °C, or, digested for 2 h with 2 units *Hinf* in 6 mM tris-HCl (pH 7.5), 6 mM MgCl₂, 100 mM NaCl, 6 mM 2-mercaptoethanol at 37 °C. Digests were fractionated on a 1.6% agarose gel (15 × 15 × 0.3 cm) using a Tris-borate buffer (Tris 89 mM, boric acid 89 mM, Na₂EDTA 2.5 mM). Current loading was at 20 mA for 30 min and then increased to 40 mA (10 V cm⁻¹) for 3 h. Gels were stained with ethidium bromide and visualised on a short wave UV transilluminator and photographed.

from the exposure times needed to produce in *M. spretus* patterns of equivalent intensity to the *M. musculus* control and by the amount of radioactivity (detected by scintillation counting) on the *M. musculus* and *M. spretus* filters.

Southern hybridisations using *Taq*I, *Alu*I, *Hinf*, *Mbo*I and *Eco*RI produced bype B patterns similar to *M. musculus* in that only a portion of the homologous sequences were cut into bands and the rest remained as a dense band close to the origin (Fig. 3*b–l*). All enzymes, apart from *Alu*I, cut a similar proportion of 'musculus' sequences in *M. spretus* to that cut in total *M. musculus* satellite: *Taq*I, ~35%; *Hinf*, ~10%; *Mbo*I and *Eco*RI, ~3% (as estimated from microdensitometer tracings). The results clearly indicate that the sites for *Alu*I are under-represented in *M. spretus*: *Hinf* and *Alu*I cut very similar proportions of *M. musculus* satellite but in *M. spretus* the bands produced from *Alu*I cuts 2–3% of the *M. spretus* sequences and *Eco*RI 1–2% approximately. With the use of double enzyme digestions (Fig. 3*c, e, h, k*) we have investigated the overlap of some of the type B segments in *M. musculus* and *M. spretus*. The data provides no evidence for a substantial overlap of the type B segments in either of the two species. In all double digests no new prominent bands were observed. Overlapping type B segments would give rise to new bands due to the presence of different type B restriction sites lying at different positions within the basic 240-base pair repeat. Furthermore, the double digest bands are of greater intensity than the single digests,

indicating that the two respective enzymes cut largely non-overlapping portions of the total population of repeats.

Our failure to detect a satellite DNA in analytical Hoechst 33258—CsCl gradients of *M. spretus* (Fig. 1*b*) suggests that although similar distributions of restriction sites have been maintained in the two sets of homologous sequences, there has also been sequence modification that now renders the two sets differentially susceptible to Hoechst 33258.

Our results suggest that there are considerable differences in amounts of satellite DNA and some differences in organization and sequence composition between the genomes of *M. spretus* and *M. musculus*. It is possible that the presence of *musculus* type B patterns in *M. spretus* indicates the earlier evolutionary introduction of these patterns in a progenitor genome. The differences in amounts would be the result of independent evolution of the homologous sequences within each of the genomes subsequent to divergence. Given the broad similarity of the relative amounts of the type B segments in *M. spretus* to those in *M. musculus*, it may be that there has been a corresponding and equivalent reduction in satellite sequences at every centromere in *M. spretus*; or, alternatively, an amplification in *M. musculus*. However, the under-representation of *Alu*I sites in *M. spretus* suggests that some chromosomal specificity may underly the overall changes. Differences in abundance of the type B segments and some differences in the frequencies of type A multimers between an
Fig. 3 Type A and type B patterns in *M. musculus* and *M. spretus*. Autoradiographs of digests of total DNA that have been fractionated on agarose gels, transferred to nitrocellulose and hybridised to ^{32}P-labelled *M. musculus* satellite. *M. spretus* lanes have been exposed 5–10 times longer than *M. musculus* to achieve a similar intensity. For clarity, different blocks of filters from the same species have been exposed for different times. Thus, for example, *M, spretus g–i* is a relatively shorter exposure than *M. spretus j–l*. All tracks have been exposed sufficiently to reveal the full arrays of bands of lower molecular weight. This has entailed a degree of overexposure of the high molecular weight material. Arrows indicate an ascending series of fragments based on multiples of a monomer length of ~240 base pairs. The multiple of the lowest arrow is indicated. Hybridization at the monomer position was barely detectable in all autoradiographs due to; first, the inefficient retention of fragments of this size during the hybridization reaction and, second, the small percentage of these fragments produced in a type B pattern (see Fig. 2*b*). Where there has been barely detectable hybridization at the monomer position this region of the autoradiograph has been omitted from some of the lanes (g–l). O indicates undigested material left near origin. a, *Ava*II; b, *Hinf*; c, *Hinf* + *Alu*I; d, *Alu*I; e, *Alu*I + *Eco*RI; f, *Eco*RI; g, *Hinf* + *Taq*I; i, *Taq*I; j, *Hinf*; k, *Hinf* + *Mbo*I; l, *Mbo*I. Purified *musculus* satellite was nick-translated^{22} with [α-^{32}P]-labelled dATP and dCTP (350 Ci mmol^{-1}; Amersham) to a specific activity of 10^8 c.p.m. μg^{-1}. Digests of total DNA (6 μg) were run on 1.6% gels with a Tris-borate buffer (see above): conditions of digestion were *Ava*II (as above); *Hinf* (as above); *Mbo*I, 6 mm Tris-HCl (pH 7.9) 6 mM MgCl$_2$, 6 mM 2-mercaptoethanol; *Taq*I, 6 mM Tris-HCl (pH 7.4), 6 mM MgCl$_2$, 1 mM dithiothreitol at 50 °C; *Alu*I, 6 mM Tris-HCl (pH 7.7), 6 mM MgCl$_2$, 50 mM NaCl, 6 mM 2-mercaptoethanol, 100 μg ml^{-1} bovine serum albumin at 37 °C; *Eco*RI, 100 mM Tris-HCl (pH 7.5), 10 mM MgCl$_2$, 50 mM NaCl at 37 °C. Digestion was with 5 units of enzyme, for 2 h. Gels were denatured and neutralized according to Southern^{23} and transferred overnight at room temperature to nitrocellulose paper (Schleicher and Schull, BA 85). Filters were baked *in vacuo* at 80 °C for 2 h. Whole filters representing 10 gel slots were hybridized with 12 ml of hybridization mixture containing 2×10^7 c.p.m. of ^{32}P-labelled *M. musculus* satellite DNA after it had been denatured at 100 °C for 10 min. Conditions of hybridization were $5 \times$ SSC, 50% formamide, 0.5% SDS at 37 °C overnight with gentle agitation. Filters were washed extensively in 3 mM Tris base (unneutralized), dried and autoradiographed using preflashed Fuji X-ray film backed by Fuji MachII intensifying screen.

isolated X-chromosome cell line and the total genome of *M. musculus* suggests that independent evolution of sequences is occurring, not only within each species genome, but also between chromosomes of a species[18].

The surprising finding, however, is that all recent sequence amplifications in either single chromosomes or in whole genomes address themselves to patterns that are already present within the genome and do not randomly generate new ones. In similar manner, recent data on the detailed organization of sequences that are shared between groups of species of Old World primates[15] and between chromosomes and species of Gramineae[24] show that there are related sets of conserved sequences, with more recent amplifications of particular sequence patterns occurring within each species or species group.

It is too early to specify the reasons for such evolutionary conservation and periodic amplifications (although speculation abounds), in our ignorance of the biological consequences of variation in types, amounts and distribution of sequence patterns. However, it seems unlikely that the differences in amount of satellite DNA in *Mus* are directly involved with the determination of chromosome homology during meiosis. These two species hybridize in the laboratory to produce fully fertile females and the species status of these two sympatric species is probably due to the evolution of premating isolation mechanisms[19].

We thank Dr Bonhomme for providing *M. spretus* livers and introducing us to his studies. S.D.M.B. acknowledges the receipt of a NI SRC postgraduate studentship.

Raman difference spectroscopy of tertiary and quaternary structure changes in methaemoglobins

D. L. Rousseau*, J. A. Shelnutt*§, E. R. Henry†
& S. R. Simon‡

*Bell Laboratories, Murray Hill, New Jersey 07974
† Department of Physics, Princeton University, Princeton, New Jersey 08544
‡ Department of Biochemistry, State University of New York at Stony Brook, Stony Brook, New York 11790

There have been several resonance Raman scattering investigations of the effect of inositol hexaphosphate (IHP) on methaemoglobins[1-5]. In those studies the sensitivity for detecting frequency differences was limited to 1–2 cm^{-1}, and consequently frequency differences were not detected although spectral intensity differences due to changes in spin equilibria were. Shelnutt *et al.* recently reported on the observation of frequency differences induced by changes in the quaternary structure of chemically modified deoxyhaemoglobins[6]. An improved Raman difference spectroscopic technique[7] with 0.1 cm^{-1} sensitivity allowed the detection of these differences. We report here the application of this technique to a series of methaemoglobins with and without the addition of IHP. In addition to the intensity changes resulting from changes in the spin equilibria, we have observed frequency differences. In all liganded methaemo-globins that we examined a decrease in frequency of the mode in the 1,370 cm^{-1} region was observed on addition of IHP. In those in which a quaternary structure change is known to occur the frequency difference is greater than 0.5 cm^{-1}. In those in which no quaternary structure change occurs [metHbA(CN$^-$) and methHbA(N$_3^-$)] the frequency difference is smaller ($\sim$0.15 cm^{-1}).

Human adult haemoglobin (HbA) was isolated and purified by standard procedures[8]. The ferric form was made by oxidation with NO$_2^-$ followed by extensive dialysis or column chromato-

§ Present address: Sandia Laboratories, D5114, Albuquerque, New Mexico 87185

graphy to isolate the purified methaemoglobin. This stock solution was stored at 4 °C until ready for use when it was diluted in 0.1 M bis-Tris buffer to yield a haem concentration of between 50 and 100 μM. When IHP was added its concentration was between 4 and 10 times the haem concentration. The ligands were added so as to attain 0.1 M levels. Resonance Raman data were obtained on previously described instrumentation designed to have a high sensitivity for detection of small differences by simultaneous data gathering from two samples and subsequent analysis on a minicomputer[6,7]. Data were obtained with 4,131 Å excitation from a krypton ion laser.

The Raman line of the porphyrin macrocycle in the 1,350–1,380 cm^{-1} region has been well characterised as an indicator of oxidation state[9], and, for low-spin ferrous porphyrins, to display a correlation with the degree of back-donation from the iron atom[10]. Shelnutt *et al.* recently reported that in deoxy-haemoglobins this Raman line is an indicator of quaternary structure[6]. They also found that in liganded proteins the line can serve as a measure of conformational stabilisation[6]. Because of these results the frequency of the line also might be expected to be sensitive to the quaternary structure change in methaemo-globins. We have examined several liganded methaemoglobins and found this to be the case.

In Fig. 1 the behaviour of the $\sim$1,370 cm^{-1} line is displayed for several methaemoglobins on addition of IHP. MetHbA(H$_2$O) and metHbA(F$^-$), both of which have a well characterized quaternary structure change on addition of IHP[11,12], show clear frequency differences of 0.73 and 0.63 cm^{-1} respectively (Table 1). The additional broad line in metHbA(H$_2$O) at $\sim$1,355 cm^{-1} in the difference spectrum results from deoxyhaemoglobin preferentially formed in the presence of IHP by photoreduction[13]. In both metHbA(H$_2$O) and metHbA(F$^-$) the addition of IHP does not result in a linewidth change but instead the entire line shifts to lower frequency. The metHbA(H$_2$O) data are displayed to demonstrate this fact by superposition of the two spectra thereby allowing visual observation that both lines have the same width and that the Raman line in the sample containing IHP has the lower frequency.

For some of the other liganded methaemoglobins, complex line-shape changes occur on addition of IHP. For metHbA(Im$^-$) there is a broadening of the line at 1,374.4 cm^{-1} when IHP is present. From optical, circular dichroism, and additional Raman
Fig. 1 Raman spectra and Raman difference spectra of the line in the 1,370–1,380 cm^{-1} region for a series of methaemoglobins with and without IHP. The line at 1,355 cm^{-1} present in the difference spectrum of metHbA(H$_2$O) results from photoreduction in the presence of IHP. The metHbA(Im$^-$) difference spectrum was balanced so as to cancel the unchanged components of the lines.

measurements it has recently been found[14] that this broadening results from a change in equilibrium in which additional metHbA(H$_2$O) is formed when IHP is added. This conclusion is supported by the difference spectrum in Fig. 1 in which a line appears at about the metHbA(H$_2$O) frequency. Because of this change in equilibrium we are unable to determine if there is a small change in frequency of the low-spin metHbA(Im$^-$) component. MetHbA(SCN$^-$) (see Fig. 1) and metHbA(OCN$^-$) are both of mixed spin character[15] and have very asymmetrical lines in the 1,370 cm^{-1} region consisting of major peaks at 1,371.7 and 1,370.7 cm^{-1} respectively, and high frequency shoulders near 1,377 cm^{-1}. As seen from Fig. 1 in metHbA(SCN$^-$) a substantial change in shape and shift in frequency (-1.5 cm^{-1}) occurs on addition of IHP. The effect of IHP on metHbA(OCN$^-$) could not be determined because carbamylation at the N-terminus inhibits IHP binding. The influence on these data of changes in spin equilibrium, changes in the relative ligand/H$_2$O binding equilibrium, and changes in binding to either the N-end or the S/O-end remains to be determined. MetHbA(NO$_2^-$) which is also mixed spin[15] and in which it is not known whether binding occurs to one of the O atoms or to the N atom gives an increased broadening on addition of IHP and a change in frequency of -0.5 cm^{-1}. On addition of IHP to metHbA(N$_3^-$) (see Fig. 1) and metHbA(CN$^-$) the frequency decreased by 0.15 and 0.18 cm^{-1} respectively.

In a preliminary experiment on the ferrous protein, HbA(NO), we found that the addition of IHP also resulted in a lowered frequency (~ 1 cm^{-1}) of the 1,375.8 cm^{-1} line and a broadening as well. A complex change of shape in this case is expected because the coordination of the iron is known to change on addition of IHP[16,17]. In a recent study by J. M. Friedman and K. B. Lyons[18] the T structure of HbA(CO) was formed by partial photolysis of HbA(CO) in conditions of low CO partial pressure. In these experiments[18] a 1–2 cm^{-1} shift to lower frequency of the 1,373 cm^{-1} line was detected.

To determine if frequency differences occurred in other Raman modes, we have examined the higher frequency region

of the spectrum of metHbA(F$^-$) and metHbA(H$_2$O) (Fig. 2). MetHbA(F$^-$) has a fully high spin ground state and metHbA(H$_2$O) has mixed spin character with a sufficiently small energy separation between the low and high spin states that the two states are populated according to their spin degeneracies at room temperature[19]. From magnetic susceptibility measurements determined by NMR[15] addition of IHP does not alter the spin distribution of either of these liganded species. With F$^-$ as the ligand, when IHP is added there is a decrease in intensity of the line at 1,478 cm^{-1}, an increase in intensity at $\sim 1,490$ cm^{-1} and a shift to higher frequency of the line at 1,564 cm^{-1}. Note, when considering the relative intensities of the 1,478 cm^{-1} line in metHbA(F$^-$) and metHbA(H$_2$O), the IHP-induced decrease in intensity of this line in metHbA(F$^-$) is consistent with a partial dissociation of the fluoride ligand and the consequent formation of metHbA(H$_2$O). Low frequency data (not shown here) on the line assigned[4] as the Fe–F$^-$ stretching mode also suggests such an interpretation. The behaviour of metHbA(H$_2$O) on addition of IHP is very different. For this case the intensities of the lines at 1,480 and 1,563 cm^{-1} increase on addition of IHP while the intensities of the lines at 1,505, 1,582 and 1,639 cm^{-1} decrease. The former frequencies correspond to the 'high spin' lines seen for example in metHbA(F$^-$) and the latter correspond to the 'low spin' lines seen for example in metHbA(CN$^-$). In spite of the qualitative difference in behaviour of these high frequency lines for metHbA(H$_2$O) and metHbA(F$^-$), the line in the 1,370 cm^{-1} region shifts to lower frequency in both cases.

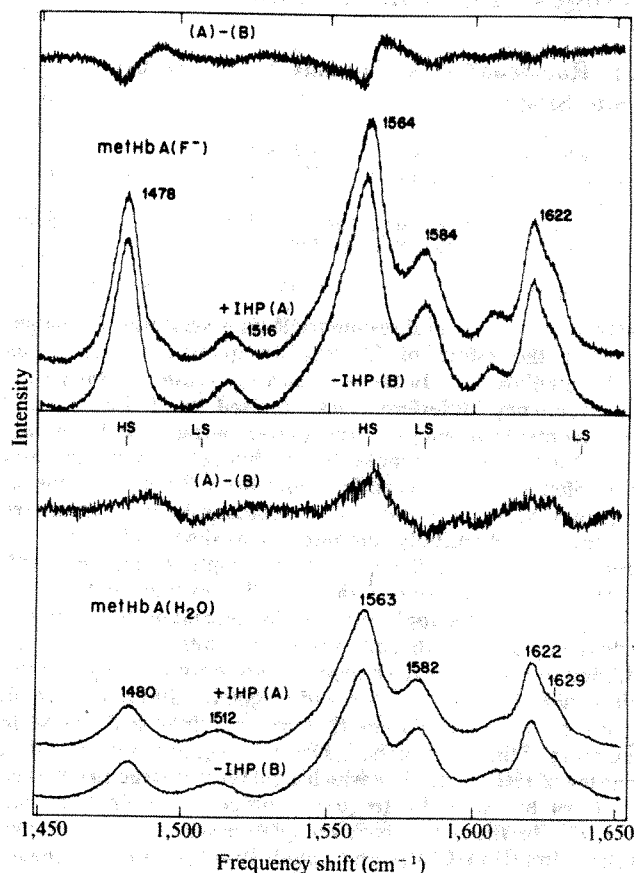
The interpretation of the IHP-induced differences in the high frequency region of metHbA(H$_2$O) and metHbA(F$^-$) is intri-


Fig. 2 Raman spectra and Raman difference spectra of the high frequency (1,450–1,650 cm^{-1}) regions of metHbA(F$^-$) and metHbA(H$_2$O) with and without IHP. The frequencies labelled HS and LS are those of high spin and low spin marker lines respectively. The scale of the difference spectrum for metHbA(F$^-$) is the same as that of the Raman spectra and for metHbA(H$_2$O) it is four times that of the corresponding Raman spectra.

Table 1 Properties of the structure dependent Raman line for several liganded haemoglobins

Ligand	Frequency	Width	IHP-induced difference
OCN^-	1,370.7	14.5	—
F^-	1,371.4	11.4	−0.63
SCN^-	1,371.7	14.5	−1.5
H_2O	1,372.0	12.5	−0.73
Im^-	1,374.4	11.5	—
CN^-	1,374.5	9.9	−0.18
NO_2^-	1,375.4	13.7	−0.54
N_3^-	1,376.1	10.6	−0.15
$NO(Fe^{2+})$	1,375.8	13.1	−1.0

The frequencies were determined from the peak positions of the lines in the absence of IHP. The widths are the full width at half height. The IHP induced differences were all determined from the intensities in the difference spectrum. No difference is reported for OCN^- because carbamylation of the N-terminal residue blocks IHP binding. No difference is reported for imidazole (Im^-) because IHP modifies the relative Im^-/H_2O to haemoglobin binding constants.

guing. The crystallographically observed structural changes at the iron in $metHbA(F^-)^{20}$ could account for the differences observed for this species. However an origin due to changes in the non-bonded interactions between the porphyrin macrocycle and the protein cannot be excluded. Observed spectral changes in deoxyhaemoglobins have been interpreted as originating from such an effect[6]. From NMR magnetic susceptibility measurements on $metHbA(H_2O)$, it was found[15] that the susceptibility is unaffected by the addition of IHP. On the other hand, from the Raman data reported here by using the $1,372 \text{ cm}^{-1}$ line as a reference we calculate a 10% increase in the intensities of the high spin marker lines when IHP is added to $metHbA(H_2O)$. Such behaviour could result from changes in iron d-level energies, but these changes might be expected to modify the spin equilibria as well, and this would be reflected in the susceptibility measurements. It seems more likely that these changes result from a direct interaction between the protein and the porphyrin macrocycle. Such an origin for the changes we observe in $metHbA(H_2O)$ also might account for the related observations in the visible absorption spectrum in which the transition in the quaternary structure from R to T produces an increase in the 'high spin' bands and a decrease in the 'low spin' bands[15]. Solvent-induced changes in the absorption spectrum originally thought to be signatures of spin state differences also have been observed in model haem compounds in the absence of spin state changes[21].

It was previously observed in deoxyhaemoglobins that the Raman line in the $1,370 \text{ cm}^{-1}$ region was sensitive to changes in protein conformation[6]. The experiments reported here demonstrate that in methaemoglobins as well this Raman line is sensitive to tertiary and quaternary structural changes. In $metHbA(N_3^-)$ and $metHbA(CN^-)$ in which quaternary structure changes do occur, we observed IHP-induced frequency differences of about 30% of the differences in $metHbA(F^-)$ and $metHbA(H_2O)$ in which quaternary structure changes do occur. This is approximately the same ratio as is observed for the UV difference spectra of these materials[11]. In those methaemoglobins in which quaternary structure changes may be brought about by the addition of organic phosphate we observe differences of greater than 0.5 cm^{-1}. The Raman difference spectra may therefore be used as a quantitative indicator of quaternary structure change.

Inhibition of photosynthesis by ethylene

S. J. Kays

University of Georgia, Athens, Georgia 30602

J. E. Pallas Jr

Little is known about how the plant hormone ethylene influences plant growth, except that it probably affects a fundamental control system. Research with inhibitors of ethylene binding and action has significantly expanded the level of understanding of the hormone. While CO_2, an inhibitor of ethylene binding, has been studied extensively[1,2] the effect of ethylene on CO_2 metabolism in photosynthesis has been virtually ignored. An initial communication indicated no photosynthetic response to ethylene by either *Pisum sativum* L. or *Zea mays* L.[3], but the exposure and the number of species tested were extremely limited. We therefore made a more extensive examination of the relationship between photosynthesis and ethylene. We report here a pronounced and reversible effect of hormonally significant levels of ethylene on the photosynthesis of the peanut.

Net photosynthesis, dark respiration and CO_2 compensation were measured on fully expanded leaves of 3-week-old plants of *Arachis hypogaea* L. cultivar Florunner. We used a semiclosed compensating system in which the amount of carbon dioxide supplied to maintain CO_2 at a given concentration was measured. Air circulated constantly through the plant chamber at 25 m min^{-1}. Chamber air temperature (25 °C) and vapour pressure deficit were controlled by the dewpoint principle, whereby humidified circulating air was brought to the desired dewpoint temperature and then reheated before entering the plant chamber. Light was provided from VHO cool-white fluorescent lamps supplemented with incandescent lamps giving $340 \mu Em^{-2} s^{-1}$ photosynthetically active radiation (PAR). The CO_2 content of the chamber was monitored by a Model 215 A-S Beckman infrared CO_2 analyser and held at a constant $300 \pm 2 \mu l \ CO_2$ per l of air by the compensating system. Carbon dioxide compensation was measured with the same system, however, without adjusting the CO_2 in the chamber.

The effects of light intensity were examined at both 1.5% and 21% O_2. We combined three sources of light: (1) the standard fluorescent–incandescent light banks used for routine plant growth; (2) 625 and 1,500 W quartz-iodine lamps; (3) a carbon arc, burning high-intensity photo 88 rods, which simulate the spectral composition of sunlight. The lowest light intensity was obtained by placing plastic shade cloth between the light bank and the plant chamber. This provided light levels of 180, 340,
Fig. 1 Effect of a 2-h exposure to various levels of ethylene on the percentage maximum inhibition of photosynthesis of peanut leaves (25 °C, 300 μl CO_2 per 1 of air).

570, 920, 1,150 and 1,400 $\mu Em^{-2} s^{-1}$ PAR, all below saturation of photosynthesis for this cultivar[6]. At any light intensity other than 340 $\mu Em^{-2} s^{-1}$, the radiant energy was applied for 15 min. Light was increased in five steps from lowest to highest. (For a more detailed description of the methods and apparatus (see ref. 4).

A measured amount of ethylene (research purity, 99.9%) was introduced into the system using a hypodermic syringe with the internal level measured chromatographically (Perkin Elmer 881, FID) every 10 min. Samples of 1 ml of air from the chamber were separated at 110 °C on a column of activated alumina (1.83 m × 3.2 mm), with flow rates of 35, 30 and 550 $cm^3 min^{-1}$ of nitrogen, hydrogen and air, respectively. During an experiment the ethylene metabolised by the plant and/or partitioned into aqueous phase was replaced.

Exposure of peanut leaves for 2 h to concentrations of ethylene (0.25, 0.50, 1.0 and 5.0 μl ethylene per 1 of air) resulted in a substantially reduced rate of photosynthesis (Fig. 1). The concentration of ethylene required to induce a decrease in photosynthesis was small and compared favourably with the concentration dependency kinetics of many ethylene-mediated growth responses[5]. A 2-h exposure of peanut leaves to 0.25 μl ethylene per 1 of air resulted in 33% of the maximum inhibition of photosynthesis, while 0.50 μl ethylene per 1 of air represented 56% of the maximum inhibition of photosynthesis.

The decrease in photosynthesis did not occur until 2.0–2.5 h after exposure and increased with length of exposure to ethylene (for example, 0.50 μl ethylene per 1 of air for 6 h resulted in a 39% inhibition in photosynthesis). The rate of photosynthesis returned to near normal with short periods of exposure (0.5–2 h) within 5 h of the initial exposure to the hormone.

Propylene, a structurally similar unsaturated hydrocarbon gas which can induce ethylene-like responses in some plants similar to that of ethylene[1], did not inhibit photosynthesis of the peanut
Fig. 2 Effect of light intensity on the inhibition of photosynthesis of peanut leaves by ethylene (1.0 μl l^{-1}) at 1.5% O_2 (25 °C, 300 μl CO_2 per 1 of air). ■, Ethylene; ●, control.

at a concentration (100 μl) propylene per 1 of air) 100 times that required to produce maximum inhibition by ethylene.

Photosynthesis was inhibited by ethylene (1.0 μl per 1) at all light intensities tested (Fig. 2); however, the percentage of total inhibition of photosynthesis remained constant at each light intensity (~18%). These data (Fig. 2) represent photosynthetic rates at 1.5% O_2, showing that the decreased rate of photosynthesis cannot be accounted for by increased photorespiration. Similar curves, at lower rates of photosynthesis, were obtained at 21% O_2.

There was a significant change in the photosynthetic compensation point (Fig. 3). Exposure of peanut leaves to 1.0 μl ethylene per 1 of air increased the compensation point from 48 μl CO_2 per 1 of air to around 60 μl CO_2 per 1 of air. Because the stomata would be open at this level of CO_2, the inhibition of photosynthesis by ethylene did not seem to involve a stomatally controlled mechanism.

A decrease of photosynthesis in *Helianthus annuus* L. was also detected, whereas neither *Pisum sativum* L. nor *Phaseolus vulgaris* L. were effected by hormonal concentrations of ethylene. From past work[5], the peanut would be expected to be the least susceptible of the three to such an effect. It has the least number of known responses to ethylene—inhibition of hypocotyl elongation and stimulation of hypocotyl diameter at 0.34 and 0.35 μl ethylene per 1 of air for 50% response saturation, respectively. The effect of ethylene on the photosynthetic rate of peanut and sunflower may be associated with their unusually high photosynthetic capacities[6,7] and is being investigated.
Fig. 3 Alteration of the photosynthetic compensation point of peanut leaves by 1.0 μl ethylene per 1 of air (25 °C).

An effect of ethylene on chlorophyll degradation has been reported at pharmacologically high concentrations[8] (>10.0 μl per 1 of air). However, based on the relatively short exposure time for the induction of inhibition of photosynthesis by ethylene (2.0–2.5 h) and subsequent recovery, it is doubtful that an alteration in the rate of chlorophyll degradation and/or synthesis could account for the response we measured. This is supported by the work of Aharoni and Lieberman[9] in which 3–4 d of exposure to 10.0 μl ethylene per 1 of air was required before a significant decrease in chlorophyll was detected in excised tobacco leaf disks. Alteration of chlorophyll degradation and/or synthesis, if it occurs in the peanut in these conditions, probably represents a secondary response which occurs substantially later than the initial molecular action of ethylene. In view of the diverse physiological responses of plants to ethylene, a more plausible explanation of the effect on photosynthesis would involve an effect on membrane permeability.

We thank D. Maxey and W. Turnbull for technical assistance.

BOOK REVIEWS

The chilling story

H. M. Rosenberg

THE application of cold impinges on modern living in many ways and in this book David Wilson, the well-known radio and television science correspondent, describes the history and current developments of many aspects of refrigeration and cryogenic technology. The book is intended for the reader who has no specialized scientific background and the presentation is indeed clear and instructive.

After the introductory chapter which describes man's success in making fire as well as using cold, we are led into the seventeenth and eighteenth centuries — the world of Fahrenheit, Réamur and Celsius. The measurement of temperatures and early methods of cooling below room temperature are described. This then leads on to a discussion on what is really meant by temperature and heat, and to the concept of an absolute zero of temperature. The third chapter is a fascinating account of the history of food preservation. The description of the development of the North American ice trade is particularly interesting. Ice was shipped not only from the northern to the southern states of the USA, but ice cargoes were even sent to India and Australia. With the increasing reliability of refrigeration machinery the ice trade declined, although natural ice was still harvested for food preservation until well into the present century. The saga of the development of refrigerated ships and the rise of the New Zealand meat industry is yet another part of the story that is extremely well told. The next stage was the mass production and distribution of frozen food to the general public. This started on a large scale with Thomas Wall's "Stop me and buy one" tricycles — 8500 of them — for selling ice cream to a mass market. But at that time few people had refrigerators and the gradual setting-up of the complete 'cold chain' from the freezing of fresh or prepared food to distribution via cold stores to the supermarket cabinet and then to the domestic freezer took another 40 to 50 years.

But nowadays we need temperatures even below that of frozen fish fingers, and the story of the liquefaction of the 'permanent gases' — nitrogen, oxygen and later on hydrogen and helium — is told with a keen sense of historical detail. It is sad to learn that Dewar, who was the first

---

Supercold: An Introduction to Low Temperature Technology. By D. Wilson. Pp.272. (Faber and Faber: London and Boston, 1979.) £8.50.

---

person to liquefy hydrogen, never really had an opportunity to score a double by liquefying helium, because of the row which developed between him and the man who had the only large supplies of helium gas in this country — Ramsay. And so credit for the first liquefaction of helium went to the great Dutch physicist, Kamerlingh Onnes of the University of Leiden, and on that date, 10 July 1908, the science of low temperature physics really began.

Although the extremely low temperatures now attainable with the liquefied 'permanent gases' catch the imagination, it is important to realize that the most widespread application of cryogenic engineering techniques is in the production and transport of gases. Gone are the heavy cylinders of compressed gas which are nearly as heavy when they are empty as when they are full. Nowadays oxygen and nitrogen are carried in bulk as liquids. Every large steel works has its liquefaction and fractionation plant in order to extract oxygen from the air — but the cold is wasted. Indeed, one of the problems of the gas producers is the surfeit of liquid nitrogen which is necessarily produced with the liquid oxygen. It is now being used as a refrigerant in the frozen food industry, in plants which shred old car tyres and as a cold bath for frozen bull semen. But by far the largest refrigeration enterprises are the plants which liquefy natural petroleum gas so that it may be stored and shipped from one country to another. The problems of liquefying and transporting such enormous quantities of potentially explosive liquid are extremely great and they have not yet been entirely overcome.

Another chapter is devoted to the problems of freezing biological material. Can we freeze living things solid, so that they revive when thawed out? There is no simple answer. Some fairly simple celled structures seem to survive freezing if they are first treated with glycerol, but whole animals, including humans, seem to be out. However it is possible to store animal embryos, thereby enabling us to ship a herd

of pedigree cattle to a far-off land in a Dewar flask of liquid nitrogen. But the storage of blood and of bull semen are the most successful products so far.

The final few chapters in the book deal with the properties of materials at liquid helium temperatures — within a few degrees of the absolute zero of temperature. From the technological angle the most exciting phenomenon is that of superconductivity — the complete vanishing of the electrical resistance in some metals and alloys. Superconductivity implies that we can pass electric currents through superconducting wires without any energy loss and this, in our conservationist world, is a very attractive idea. But although small prototypes of superconducting generators and motors have operated satisfactorily we are still some way from seeing a large superconducting generator in a power station. The prospect of a superconducting motor in a ship is intriguing — let us hope that sufficient funds will be made available to try it out! By far the most successful application of superconductivity up to now has been in the construction of extremely powerful electromagnets — magnets which produce fields which were almost unrealizable about 10 years ago are now available at a very reasonable cost. One exotic application of superconductivity which is not described and which should have been mentioned is the Japanese magnetically-levitated train using superconducting coils. A small prototype has been operated successfully. Computers with a very high packing of elements made from superconducting junctions seem to be promising but with these, as with any other application outside the scientific laboratory, the need for utter reliability is paramount, and it is far harder to make things foolproof at the temperature of liquid helium than at room temperature.

How low a temperature can we reach? To a certain extent it depends on what is meant by temperature. The lowest temperature to which a complete system in thermal equilibrium has been cooled is probably just below a thousandth of a degree, but a sub-system of nuclear spins can be magnetically aligned so that the effective temperature is only about a millionth of a degree above absolute zero.

Besides superconductivity other remarkable things happen at low

temperatures. There is the analogous effect in liquid helium which becomes superfluid at 2.17 K and for which we still do not have a completely satisfactory explanation. And, still colder, we have the remarkable series of changes which occurs in the light isotope of helium — liquid helium three.

This is a book which whets the appetite. The treatment is simple and yet the explanations are not so oversimplified that they would worry a scientist. Occasionally the broadcasting voice of the author comes through a little too strongly so that the excitation and marvelling at new phenomena or techniques, which is very necessary via the microphone, is perhaps a little bit too enthusiastic in print. But this is only a minor point. David Wilson has done a good job and it is evident that he enjoyed doing it.　　　　　　　　□

Molecular optical activity

S.F. Mason

FOR Louis Pasteur, the non-superposability of mirror-image molecular structures was the primary characteristic of natural products, as opposed to synthetic substances, and the distinctive physical property of handed molecules, their optical activity, provided him with a demarcation criterion between chemistry and life. The investigation of the optical rotatory power of chiral molecules, fundamentally, their differential interaction with left- and right-circularly polarized light, played a central role in the development of stereochemistry during the nineteenth and early twentieth centuries. From the 1950s, however, the chiroptical methods became increasingly overshadowed by more sophisticated physical techniques in structural chemistry, and their particular value in problems concerned with chiral recognition and discrimination was sometimes overlooked. The thalidomide tragedy, for example, could have been averted if this synthetic racemate had been separated into its optical isomers, for only the left-handed (S)-(–)-isomer has teratogenic properties. While occupying a subsidiary place in mainstream chemistry from the 1950s, the study of the electronic and structural basis of optical activity has proliferated at the periphery, in biophysics, biochemistry and chemical physics. The present book was written from the Laboratory of Chemical Physics, NIH, Bethesda, and the majority of the current theories of optical activity reviewed were first published in the *Journal of Chemical Physics,* rather than the orthodox physical chemistry journals.

The author's primary aim, which has been largely achieved, is the systematic development of the fundamental principles underlying the modern theory of the optical properties of chiral molecular structures, and of the derived semi-empirical models employed in the stereo-chemical and other applications of chiroptical spectroscopy. After an introductory historical survey, the classical and the quantum theory of the interaction of an assembly of molecules with electro-magentic radiation is discussed, with the extension beyond the standard treatment required to account for optical activity, namely, the explicit consideration of terms dependent upon the ratio of the molecular dimensions to the wavelength of the radiation. The particular approximate models covered are those of the 'symmetric chromophore', or light-absorbing group, bonded to a dissymmetric array of substituent groups in a chiral molecule, the 'coupled chromophore pair' of a chiral dimer, and the general but more miscellaneous case of the 'inherently dissymmetric chromophore'. A group-theoretical treatment of chirality follows, with applications to the sector rules connecting the stereochemical configuration of an enantiomer with its rotary strength in a given electronic transition. There is a minor confusion in this section. The second of the three classes of point group symmetries listed (p.152) should be partitioned between the first and the third, since there are but two classes, chiral molecules with pure rotation symmetry and achiral structures with rotation–reflection symmetry, which implies the super-posability of the mirror-image forms. Subsequent chapters are devoted to individual chromophore systems, the optical activity of polymers and of orientated molecule assemblies, and to recent developments. The latter include luminescence- and fluorescence-detected optical activity, and, more particularly, vibrational optical activity in both infrared absorption and Raman scattering spectroscopy.

The book is well illustrated, with a good selection of relevant absorption and circular dichroism spectra, and contains useful appendices of technical terms and of the unit systems in current use. It is recommended to all research workers concerned with chiroptical spectroscopy, as well as for general library reference.　□

Insight into disorder

Praveen Chaudhari

IN THIS book, Professor Ziman presents the first comprehensive and systematic review of the theoretical literature on the major forms of disorder. It is a remarkable book, both because of the subjects covered and because of the insight that the author brings to bear in explaining the generality and limitations of theoretical models.

The various forms of disorder are reviewed in the first three chapters. Chapter 1 is concerned with disorder where an underlying lattice can define the spatial arrangement of atoms. For example, compositional disorder in an alloy or spin disorder in an Ising model. This chapter contains a theme that is often repeated in the book — that of showing how the same mathematical model can be used to describe a number of situations which initially appear to be unrelated. In this instance the simple Ising model Hamiltonian is shown to apply to atomic interactions in a binary alloy. Its applicability to ferroelectric solids is briefly narrated. Chapter 2 deals with topological disorder characteristics of amorphous solids and liquids. Following a review of how the nature of disorder is described and modelled, there is a section on the analytical theories of the liquid state. In a natural progression, Chapter 3 contains a review of the statistical properties of random fields in continuous approximation. Chapter 4 has a brief and compact description of diffraction theory used in the study of disorder by experimental techniques. This is not a chapter that one can read and perform an experiment but rather one which contains the underlying physics and limitations on the information that can be extracted.

Chapter 5 has a detailed discussion of substitutional disorder. The success and limitations of the mean field approximations, the quasi-chemical approximation, the Bethe lattice and the pseudo-assembly method of Kikuchi are described. From these approximate solutions the author moves towards exact solutions of the one- and two-dimensional Ising model. The difficulties with obtaining a solution of the three-dimensional Ising model are touched upon and graphical methods are introduced. The chapter concludes with a succinct review of scaling and renormalization developments of the last few years. Chapter 6 deals with the thermodynamics of topological disorder. As in the preceding chapter, Professor Ziman begins with one-dimensional topological order and shows how genuine topological order cannot be

present in such models. He then proceeds to analyse the various approximations (for example, the van der Waal or the Percus-Yevick) used in coping with the difficult three-dimensional topological disorder. The role of computer simulation techniques in melting and the liquid state is emphasized, and the chapter concludes with a short discussion of the configurational and communal entropy and free volume.

Chapter 7 summarizes the statistical properties of polymers in solution. Branching, gel formation, rubber elasticity and random walks are some of the topics covered. The statistical treatments of the gels are connected to the Bethe lattice and the percolation problem. Chapters 8, 9 and 11 are concerned with excitations — magnons and phonons — in disordered solids. Chapter 8 develops the notion of localization or gaps in the spectral density using a linear chain model, and in Chapter 9 the discussion is extended to the three-dimensional case. Here the tight bonding and coherent potential approximation are discussed in some depth. Anderson localization and percolation theory and their significance in our understanding of disordered solids are presented. Chapter 11 contains a review of the dynamics of liquids and glasses.

Chapter 10 has a derivation of the resistivity equation (the Ziman formula) frequently used by experimentalists to explain the resistivity data on glasses and liquids. The generality and applicability of this deceptively simple formula is discussed. The remaining part of this chapter is concerned with scattering theories and their application to disordered solids. Chapter 12 contains a rather brief description of spin and ferromagnetic glasses. There is no mention made in this chapter of recent theoretical developments in spin glasses using topological notions. The final chapter contains the theory of metal–insulator transition and hopping conductivity.

Professor Ziman's book is primarily aimed at theoretical physicists. For readers with such a background or interest the book provides excellent reading of the current status of the field of disorder. The limitations of theoretical approaches, which are frequently assumed in the original sources, are clearly stated.

There are, however, a few areas which are either not adequately covered or are omitted entirely. Superconductivity and optical properties of disordered solids are not discussed. The theory of structural defects is barely mentioned. Considering the amount that has been covered these omissions are, perhaps, understandable. Overall, this book should be a very useful acquisition to anyone who is interested in the field of disorder.   □

Nuclear theory

Norman K. Glendenning

Nuclear Physics with Heavy Ions and Mesons. Edited by R. Balian, M. Rho and G. Ripka. Vol. I, pp.432; Vol. II, pp.548. (North-Holland: Amsterdam and New York, 1978.) Vol. I £66.75, Dfl.150; Vol. II $80, Dfl.180; two volume set $133.25, Dfl.300.

IN THE last half dozen years or so, the subject matter of nuclear theory has expanded remarkably, and no volumes that I know of chronicle this better than do these. The modern theoretical nuclear physicist becomes more and more a theoretical physicist as the techniques and concepts that he develops or borrows from other disciplines to understand nuclear behaviour under unusual conditions make intimate connections with other branches of physics. The articles are all excellent.

Volume I deals with collisions between heavy nuclei from low to relativistic energies. Semi-classical theory for peripheral low-energy collisions is developed in several powerful approaches. The richness in behaviour of nuclear material under the stress of more intimate reactions or rapid rotation, or under the impact of relativistic collision, is the main subject.

For me, Vol. II is more exciting, perhaps only because the material is less familiar, but I think also because it indicates a new frontier of nuclear physics, where it blends with particle physics and with astrophysics. By now my copy is well worn. Most of this volume treats nuclear matter in the framework of a relativistic field theory for the light mesons and baryons, as is appropriate for studying new phases of matter at densities higher than normal such as exist in neutron stars or fleetingly at the site of a collision between nuclei at relativistic energy. This volume will be difficult going for the traditional nuclear physicist, but it opens the door to a new world.

The editors and authors are all to be congratulated for a fine work.   □

Norman K. Glendenning is Head of the Nuclear Theory Group at the Lawrence Berkeley Laboratory, University of California.

Three on food and land use

Joseph Hutchinson

The Growth of Hunger. By R. Dumont and N. Cohen. Pp.229. (Marion Boyars: London, 1980.) Paperback £3.50. *Green and Pleasant Land?: Social Change in Rural England.* By H. Newby. Pp.301. (Penguin: Harmondsworth, UK, 1980.) Paperback £2.50. *Farmland, Food and the Future.* Edited by M. Schnepf. Pp.214. (Soil Conservation Society of America: Ankeny, Iowa, 1980.) $8.

I THOUGHT *The Growth of Hunger* was about hunger in the world getting worse. It is not. Repeatedly this is assumed, but nowhere is there any documentation of the extent of hunger, or any hard evidence given that it is more widespread now than it used to be. The book is, in fact, an attack on landlords, colonialism, the market economy, the Green Revolution, agrochemicals, multinational corporations, and poverty and injustice in society. There is already an extensive literature in this vein, and *The Growth of Hunger* does not add usefully to it.

In *Green and Pleasant Land?*, Howard Newby, after a decade of research into social change in rural East Anglia, writes perceptively, cogently, and with sympathy but not emotion. After an introductory chapter there are chapters on land and land ownership, the farming industry and the rise of agribusiness, and the farm worker and the drift from the land.

There follow two chapters on the new influences that threaten the dominance of the agricultural interest in rural affairs. First is an account of the migration of urban-based families to rural domiciles, and second a discussion of the growth of environmentalism and its challenge to the privileged position of farming in planning legislation.

Newby probes deeply into the rural situation, and exposes the impotence and the growing isolation of the rural poor. The in-migration of urban people has generated a new affluent component in the rural population, and increased the polarization between rich and poor. With their cars and their town associations, the incomers have no difficulty in avoiding the isolation of the countryside, and they offer little support for rural services.

The incompatibility between the needs of the underprivileged and what it is economic to provide, is matched by the inconsistency between what the environmentalists regard as good and the agribusinessmen find is profitable. And having lucidly described these dilemmas, Newby leaves us. He has written a very good book, but now will he please write another. The conclusion I draw from *Green and Pleasant Land?* is that the social scientist — if he is as good as Newby — should advise us on what we should do, and the economist should then tell us what it would cost, and how we should pay for it.

Farmland, Food and the Future has nothing of the unity and coherence of *Green and Pleasant Land*. It is a series of essays sponsored by the Soil Conservation

Society of America on the loss of farm land to other uses. It was planned to draw attention to the facts of the loss of farm land, chiefly for urban uses, to consider whether they constituted a serious problem, and to report on what is being done about it. The essays are timely, since it is clear that the loss of farm land has only recently become a topic of concern in America, and there is not yet an agreed evaluation of the situation.

It is interesting and significant to compare the situation in the USA with that in England described by Newby. Many factors are similar. In both countries the erosion of farm land to meet the demands of urban users is very great, and losses are heaviest from the best land categories. Both have experienced a long-continued drain of the rural population to the towns, and equally they now have to accept a reverse migration. Indeed, they are also alike in the propensity of the urban migrants to become defenders of the sanctity of the countryside. To quote: "Oregon is the victim of tremendous in-migration, yet the newest immigrant is the first to want to slam the gate".

There are also fundamental differences. The underprivileged farm workers are the historical consequence of the 'Master and Man' structure of English farming, which has no counterpart in the 'Family Farming' tradition of America. The American urban sprawl has been largely forestalled in England by planning legislation that would in America be an infringement of rights of property.

These essays will help to crystallize what is at present a rather amorphous debate.

Sir Joseph Hutchinson is Drapers' Professor of Agriculture Emeritus at the University of Cambridge, UK.

Flood adjustment

Malcolm D. Newson

Human Adjustment to the Flood Hazard. By K. Smith and G.A. Tobin. Pp.130. (Longman: Harlow, UK, 1979.) Paperback £3.95.

THE reviewer has just spent 48 hours monitoring the silt load of a Welsh river in high flood but, along with others who study the purely physical properties of flooded rivers, he is almost ashamed of the satisfaction such studies provide; to the general public and especially to those who suffer from disruption, damage or even bereavement from floods, they are nothing more nor less than a hazard to life. The authors' premise for this book is that the physical approach to floods, which has its eventual utility in incorporation by engineers into flood protection schemes, is divorced entirely in this country from the behavioural approach.

They begin their book by describing the flood as a hazard, adding financial figures in pounds or dollars lost by flood damage — as we all do these days to point to an economic justification for research! However, the striking thing is not that floods comprise 30% of all natural disasters, nor that they may be increasing in frequency, but that Man courts disaster so assiduously by developing floodplain sites for housing and industry. The book divides the remedies society provides into structural (mainly engineering solutions, but including land-use control upstream of the floodable area) and non-structural (insurance, flood-zoning and the fast-developing field of flood forecasting are included). By the middle of the book the largely review material is dispensed with in favour of a statement of the ideal form of comprehensive floodplain development, one in which hydrological technology is matched, not only with cost-benefit analysis, but also with studies of social feasibility and the whole operated on a planned basis. The original material, researched along the River Eden in Cumbria, describes how both Appleby (a loss-bearing upland case) and Carlisle (a case of muddled floodplain adjustment) treat the threat of flooding from the Eden. The date of the most recent damaging flood is important in both local and regional studies (on the Eden it was 1968) and this makes the reviewer very anxious about how flood adjustment studies can ever become more widespread.

Other doubts about ever attaining the authors' ideals come from questionnaire survey results, illustrating just what an unmanageable lot we all are when confronted by hazard! Just as planner will never get all the people in one road to have grey front-doors they are unlikely to standardize the response to hazard. Here the authors' use of the word 'authoritarian' response to describe 'official' response to floods produces a shudder that the cure might be worse than the ailment!

Admitting the bias of the reviewer, it is of great interest to read that advances in hydrology and in technology have now given Britain something of a lead in flood warning; after the Lynmouth disaster in 1952 no-one in the water industry believed we would ever be in a position to give an hour's warning of flooding; but now we could.

The book is well illustrated, copiously referenced and shows that, whilst the engineer and sociologist do not seem to be talking, the geographer holds a substantial key; will it be used to open doors outside Eden? □

Malcolm D. Newson is Resident Hydrologist at the Institute of Hydrology, Plynlimon, UK.

Protologic

Peter Bryant

The Origins of Logic (Six to Twelve Months). By Jonas Langer, Pp.437. (Academic: New York and London,1979.) $26.50, £15.

QUITE a common move in psychological research with babies these days is to look for what are called 'precursors'. The idea, most frequently applied to language acquisition, is that the things babies have to do and particularly the social routines which develop between them and their parents are sufficiently complex for them to pick up certain abstract rules which will help them a year or so later on when they begin to learn grammar. Analogies are made between the rules of the earlier social habits and grammatical rules, and it is argued that the one lays the basis for the other. This argument is often used in attacks on Chomsky's idea of an innate language acquisition device. The rules are learned not innately, it said, but they are learned before. The argument is attractive, but it has the flaw that it is very difficult to support empirically. How do you establish a causal link between the earlier and the later events? Simply to appeal to an analogy between the two is glib.

The same unsolved problem, as well as several others, stalks the pages of Professor Langer's book, which is an attempt to discover the precursors of logic. He gives babies in their first year sets of objects to play with. If they put two things together here is said to be the precursor of addition — protoaddition it is called. Protosubtraction, protomultiplication, proto one-to-one correspondence, protoinference follow thick and fast. When a six-month-old baby puts a brick in his mouth, takes it out, but leaves his mouth open we are told that this is protosymbolic behaviour, because the gesture is detached from the object. The author hardly considers the possibility that what the babies are doing has nothing to do with logic, and he never questions his often-repeated assertion that the experiences they have playing with objects lays the basis for their later understanding of logic. Yet he gives no evidence, because no evidence is possible, for this central assumption. The observations are often acute, but the assumptions behind them, hedged though they are with impressive terms and often impenetrable prose, are very insecure. □

Peter Bryant is in the Department of Experimental Psychology, University of Oxford, UK.

OBITUARY

Roy Markham

THE DEATH of Professor Roy Markham, Director of the John Innes Institute, on 16 November 1979 has deprived us of a scientist who made outstanding contributions to research in several quite different experimental fields. He was born in London on 29 January 1916, the son of A.C.C. Markham, and educated at St Paul's School. In 1935 he entered Christ's College, Cambridge and read biochemistry for Part II of the tripos. After graduation in 1938 he decided on a research career, joining N.W. Pirie in the biochemistry department. In 1940 he joined Kenneth M. Smith at the Plant Virus Research Station which was then under the auspices of the Ministry of Agriculture.

By modern laboratory standards the available facilities at the Plant Virus Research Station were very primitive. They consisted of a few glasshouses and part of a wooden potato storage shed which had neither heating nor running water. However, they were fortunate enough to be allowed to continue making use of a room as a laboratory at the top of the Molteno Institute, previously allocated to Professor David Keilin. In this room, together with some additional facilities made available on the Downing site, Roy Markham laid the foundations for his later achievements. By 1942 he had already developed a steam distillation apparatus suitable for micro-Kjeldahl analysis which was subsequently listed under the British Standards Institute B.S.1428.

In 1940 Kenneth Smith was working with a new plant virus (turnip yellow mosaic) which was shown to have several interesting properties. Roy Markham became particularly interested in the physico-chemical properties of this and other small plant virus particles which stimulated his interest in the problem of high speed centrifugation. He had a genius for improvising and was highly skilled in making his own apparatus from bits and pieces found in the laboratory. An air driven high speed centrifuge was one of the devices he constructed to isolate virus particles.

It was soon realised that highly concentrated virus suspensions could be produced with a high speed centrifuge, and it was relatively easy to purify the virus with ethanol and half saturated ammonium sulphate. These highly concentrated suspensions led to the formation of octagonal crystals and this virus was one of the first (if not the first) insect-transmitted (flea beetle) viruses to be crystallised.

A number of important results emerged

from these early experiments; it was shown that turnip yellow mosaic virus could be separated into two fractions which were named "top" and "bottom" components. At the time there was considerable controversy concerning the presence of nucleic acid and its significance in virus particles, but Roy Markham clarified the issue by establishing that the "bottom" component containing the RNA was highly infectious whereas the "top" component devoid of the nucleic acid was non-infectious.

In 1945 the research came under the aegis of the Agricultural Research Council and the Plant Virus Research Unit was established. Roy Markham became increasingly involved with the physiocochemical properties of plant viruses. Kenneth Smith concentrated more on the biology, ultrastructure and transmission of plant and insect viruses. However, Roy Markham, together with Ellis Cosslett were among the first investigators to record electron micrographs of plant virus microcrystals.

He will be particularly remembered for his work on viruses when he was joined by J.D. Smith and R.E.F. Matthews. They formed a most fruitful collaboration, producing a series of important publications which established the composition and properties of several plant viruses. He was elected Fellow of the Royal Society at the early age of forty.

His interest in electron microscopy started when examining air-dried and unstained samples of viruses in an early RCA machine which was installed in the Cavendish Laboratory. Although many biologists were highly critical of the images produced from early studies in electron microscopy, Roy Markham quickly realised the powerful potential of applying these instruments to the structure and measurement of virus particles. When the Plant Virus Research Unit was fully established at the University Farm in Huntingdon Road, Cambridge, the laboratory possessed one of the first production electron microscopes. In addition, extensive research facilities were made available with the aid of various grants Roy Markham had obtained in support of the expanding virus research programme.

Kenneth Smith retired in 1959 and Roy Markham became Director of the Plant Virus Research Unit. The work continued to expand and a regular flow of visiting scientists came to his laboratory. His interest and enthusiasm for developing and building apparatus gathered momentum as war surplus equipment continued to

provide an ideal source of materials. The symmetry associated with the architecture of virus particles together with their repeating features stimulated him to construct a device which allowed the regular structural features of viruses recorded in electron micrographs to be averaged and subsequently reinforced. The technique was established as the "Markham averaging method". In addition he investigated the potential of image analysis by building a simple ultra-violet light optical diffractometer for recording the diffraction spectra from electron micrographs and making accurate measurements.

There will be very many visitors to the Plant Virus Research Unit at Cambridge who will remember the warm welcome and hospitality they received from Roy and Margaret (née Mullen whom he married in 1940), who enjoyed entertaining their guests in a most elegant style. Roy Markham had a lighted-hearted approach to research, coupled with an infectious sense of humour which visitors from abroad found difficult to appreciate on first impression, and it must be said led to some misunderstanding on more than one occasion.

In 1967 the Directorship of the John Innes Institute fell vacant at a time when a decision had been made to move the institute from Bayfordbury in Hertfordshire to Norwich. Roy Markham was invited to fill the post, and saw an opportunity to create an unique centre for research by proposing that an institute could be established by moving the Plant Virus Research Unit in Cambridge to form part of the John Innes Institute at Norwich. This resulted in a considerable undertaking, as Roy Markham became involved in the planning of a large complex of laboratories and ancilliary services. The John Innes Institute brought together under Roy Markham's Directorship and guidance during a period of just over ten years, has been re-established as a centre of international standing.

It is characteristic of Roy Markham that he left little record of his life, apart from his collection of scientific and administrative material. Although he had relatively few interests outside the laboratory, he devoted a great deal of his spare time at home to designing and constructing experimental apparatus for people within the institute. During his long illness he persisted until the end in working on a second and more advanced device for the processing of electron microscope images with the aid of computers.

R.W. Horne

T. L. McMeekin

THOMAS LEROY MCMEEKIN, commonly known as "Mac" to his friends, died in Columbia, South Carolina on 11 November 1979. He did notable work in protein chemistry over more than three decades, first in academic research and later as the head of an important government laboratory.

Born on 8 May 1900 in Monticello, South Carolina, he took his PhD at the University of Chicago in 1925, under the direction of Professor F. C. Koch, his thesis dealing with the purification of pepsin. In 1928, he joined the Department of Physical Chemistry at Harvard Medical School, headed by Professor Edwin J. Cohn. Cohn, whose primary concern was with the physical chemistry of proteins, was then engaged in purifying the substance in liver that was active in the treatment of pernicious anemia. This program achieved a clinically effective liver extract, though it failed to overcome the formidable problem of isolating what was much later to be known as vitamin B_{12}. McMeekin played a central part in this work, but his major contribution came in studies on the physical chemistry of amino acids, peptides, and a wide variety of related molecules.

This cooperative enterprise involved Cohn, J. P. Greenstein, myself and other members of the laboratory, together with George Scatchard and John G. Kirkwood at MIT, and Jeffries Wyman at the Harvard Biological Laboratories. McMeekin's role was primarily in the choice and synthesis of a wide variety of organic compounds, chosen to define the relations between structure and relative solubility in water and organic solvents, and other properties such as partial molal volumes. The aim was to provide a basis for interpreting the unusual properties of amino acids and peptides, and (by implication) of proteins, in terms of their content and arrangement of polar, non-polar, and electrically charged groups. McMeekin's work was essential to all this; in particular his studies on the influence of non-polar groups on solubility in various media provided fundamental data and systematic relations for the understanding of what later came to be called hydrophobic interactions. In studies on proteins, he achieved the crystallization of two forms of albumin from horse serum.

In 1940 he joined the Eastern Regional Laboratory of the U.S. Department of Agriculture in Philadelphia, and later became director of its Protein Division. With R. C. Warner in 1942 he carried out a fundamental study on the hydration of ß-lactoglobulin crystals, showing for the first time that it was possible to study protein crystals by direct analysis of water, salt, and protein, and to relate the composition of the crystal to that of the surrounding medium. His studies on milk proteins — notably on β-lactoglobulins and on the separation and characterization of several components of casein — led to his receiving the Borden Award in 1950. Other important contributions from his laboratory involved the preparation of new types of protein fibers and study of partial specific volumes of proteins in relation to their structure.

On retiring from the Protein Division in 1965 he became Research Professor of Biology at the University of South Carolina in Columbia until 1972. He spent his last years near by, in Monticello, his birthplace, remaining active and alert until his final brief illness.

He was twice married, first to the late Vera Crockatt, and subsequently to Crystal Stribling, who survives him. He had two daughters and a son by his first marriage. One daughter, Dorothy McMeekin, is Professor in the Department of Natural Science in Michigan State University at East Lansing.

McMeekin was modest and gentle in manner; but his strength of character was obvious to those who knew him. He was ever helpful to his colleagues and to younger co-workers. He had an excellent quiet sense of humour, and a shrewd eye for the strengths and weaknesses of other human beings. Above all he was a man of complete integrity, who will be remembered with admiration and affection, especially by that band of protein chemists of which he was a distinguished member.

John T. Edsall

H. H. Plaskett

WITH THE DEATH of Professor H. H. Plaskett on 26th January 1980, Britain has lost one of its most distinguished astronomers.

Harry Hemley Plaskett was born in 1893, the elder son of Dr J. S. Plaskett, who later became Director of the Dominion Astrophysical Observatory in Victoria, B.C. After service in France during the First World War, Plaskett joined his father's observatory as a staff member, where he remained for eight years until he became Professor of Astrophysics at Harvard in 1928. He was appointed Savilian Professor of Astronomy in Oxford in 1932, but his productive years were again interrupted by war service between 1939 and 1944. Part of the later years of the war were spent by him in developing a new type of sextant for the Ministry of Aircraft Production, which was in constant use until quite recently.

Almost the whole of Plaskett's working life was spent in astronomical spectroscopy, beginning during his years in Canada with stellar spectroscopy and his pioneering work on the emission spectra of gaseous nebulae. He had always recognised the importance of solar studies as a basis for understanding stellar atmospheres, and remarked in 1931 that "spectroscopic investigations of the sun seem likely to yield more information about stellar physics than spectroscopic studies of the stars themselves". In this year he published his classical observations of the variation of the profiles of the Mgb lines across the solar disk. This was an important step forward in astrophysics which involved the development and application of new and accurate techniques of spectrophotometry, many of them devised by Plaskett himself especially for this study. It also came at an appropriate time because of parallel work on the theory of line formation in stellar atmospheres being conducted by Eddington and Milne, following earlier work by Schuster. Plaskett's comparison of theory and observation led to a first good understanding of the mechanisms by which stellar spectrum lines are formed.

On his appointment at Oxford, Plaskett decided to devote himself wholly to solar studies. To this end he built an advanced solar telescope with a high dispersion spectrograph at the observatory. With it he planned a series of observations of photospheric mass motion through the Doppler displacements of special lines. Although this work was soon stopped by the Second World War, he felt so much encouraged by its progress after the war that he built a second solar telescope of aperture 20 in and focal length 35 m, complete with a fine spectrograph. With this he resumed his work on solar mass motions, the results of which, and their interpretation, were presented in a well known series of papers. During his 28 years in Oxford, Plaskett built up a small but distinguished group of solar astronomers, which was strengthened through close contacts with mathematicians and theoretical astronomers in other departments of the university. Over the years, many astronomers became indebted to him for the great help they received, and many owed the start of their careers to him.

Plaskett had a considerable influence on the development of astronomy in Britain. In a celebrated Presidential Address to the Royal Astronomical Society in 1946, he proposed the building of a large optical telescope in Britain. This resulted in the construction in 1968 of the 98 in Isaac Newton telescope at Herstmonceux, which is now soon to be moved to the new Northern Hemisphere Observatory in the Canary Islands.

After his retirement, Plaskett continued to work in the Department of Astrophysics and he worked regularly with the 20 in telescope until the age of 84 years. He was elected a Fellow of the Royal Society in 1936 and was awarded the Gold Medal of the Royal Astronomical Society in 1963. He is survived by his wife Edith, and his son and daughter.

D.E. Blackwell

Banking DNA sequences

MOUNT Everest, as we all know, was first climbed "because it was there". The Everest of those scientists who are devoted to the sequencing of DNA is the complete human genome, a peak that cannot yet be conquered. Nevertheless it seems not out of the question, even now, to attempt to sequence a single chromosome from man or Drosophila; or at least to tackle a substantial fragment of one such chromosome. And certainly some of the more ambitious sequencers would no longer consider the complete genome of the bacterium *Escherichia coli* to be a sufficient challenge to their skills.

The reasons why grandiose sequencing can now be contemplated are technical. In the early 1960s when Walter Fiers embarked upon the, then, highly ambitious project of sequencing the first complete genome, that of the bacterial virus MS2, it was not possible to sequence fragments of longer than eight nucleotides at one time. The complete structure of the 3,569 nucleotide genome of MS2 was published in 1976. Now, thanks largely to techniques developed by Alan Maxam and Walter Gilbert in Harvard and by Fred Sanger and his colleagues in Cambridge, one can sequence stretches of up to 250 nucleotides at a time. The sequencing of MS2 would now be no more than a single PhD project in a laboratory where the necessary techniques were already in operation.

Rapid sequencing, however, is only half the trick. One needs also relatively large amounts of pure DNA to be sequenced. For that, the techniques of cloning recombinant DNA in bacteria have been invaluable.

The combination of rapid sequencing and cloning has made it feasible to tackle larger and larger genomes. Following MS2, there came the bacterial virus ΦX174 and the mammalian SV40, polyoma and hepatitis viruses. In the offing is the complete sequence of several more viruses, led by adenovirus, and that of the genome of mammalian and yeast mitochondria. In quantitative terms this is progress from the 3.6 kilobases (one thousand nucleotides) of MS2 to the 5.4 kilobases of ΦX174, through the 35 kilobases of adenovirus to the 50 kilobases of yeast mitochondria.

By contrast the complete genome of *Escherichia coli* is about 10,000 kilobases, the Drosophila genome an order of magnitude greater and a single human chromosome some 500,000 kilobases of DNA. With a realistic outlook the *Escherichia coli* sequence could be completed by a team of ten in less than five years; with an optimistic one, a tenth of a human chromosome would not take as long because the very thought of devoting a lifetime to the task would force an order of magnitude increase in the speed of sequencing!

The dilemma for sequencers deciding what to tackle next is that, whereas a new graduate in the right laboratory might immediately stumble upon an iconoclastic stretch of DNA, so might a bevy of experts take several years to reveal nothing more than another 1,000 kilobases of uninteresting sequence.

Not that it is possible to overestimate the astonishing discoveries that have emerged, unsuspected, from sequencing: overlapping genes, split genes, degenerate genes and the bizarre features of the mitochondrial genome, including a genetic code that breaks the rule that the code is universal.

As with so much in science, hunches may be the only way to make decisions, be they by project leaders or grant givers.

From any large scale sequencing there now arises a series of irritating problems. The first is in what quanta to report the sequence; gene by gene or only when the sequence of the whole genome is essentially complete? In theory the latter approach is preferable, unless any particularly interesting feature is revealed along the way. But can the pressure to milk a sequence for as many papers as possible, or even just one for each collaborator, be resisted?

Then there is the problem, faced by journals, of printing screeds of ATCG permutations, less appetising to those who have not acquired the taste, than even the stock exchange page of a newspaper. The temptation — perhaps to be resisted — is to photo-reduce them to near-illegibility. Worse only is the suggestion, sometimes voiced, that sequences should be available from the author, but not be published at all. That would serve the thinking reader about as well as does television's The Forsyte Saga act as a guide to Galsworthy's literary style.

Finally, one major problem arises from the quantity of sequencing that has already been amassed — of the order of 100 kilobases — let alone that which the next few years will bring. The problem is how best to collate as much data as possible so as to bring out salient features. Although number, or rather letter, crunching is no substitute for thought, nevertheless computers are an essential aid to sequence collation. Already they are needed in any large scale sequencing simply to piece together the data obtained from the sequencing of random fragments of large genetic units. What does not yet exist is any central data bank in which all sequences could be deposited and made freely available to the whole scientific community. There are good precedents for such a service in the Brookhaven Protein Data Bank and the Cambridge Crystallographic Data Centre. The need for a DNA sequence bank is becoming urgent. At its best it would operate on a computer network system and offer search programme facilities. At its most meagre it would be no more than a depository, run by a keyboard operator, which sent out tapes for a nominal fee. Proposals to start some kind of bank in the US have been in the air for at least a year, and last week the European Molecular Biology Laboratory veered towards a decision to start one. It matters little by whom, or where, a bank is started. What is important is that it should start soon. □

United States

More tests required on new chemicals

THE Environmental Protection Agency has for the first time used its powers to block the introduction of new chemicals, which have not been tested sufficiently for safety.
David Dickson reports

EVER since the Toxic Substances Control Act (TSCA) was passed by Congress in 1976, it has remained the centre of fierce controversy. The chemical industry has claimed that many of its rules on new and existing chemicals impose an unduly harsh economic burden; environmentalist groups argue that the Environmental Protection Agency has been dragging its feet in enforcing the Act.

Now the Agency has decided to bare its teeth. Under a section of the Act requiring all companies to provide pre-manufacturing notices (PMNs) containing data on safety tests before a new chemical is introduced, the EPA last week announced that it was blocking the manufacture of six chemicals for which it felt that data submitted were inadequate.

The name of the company is being withheld at its request. However the EPA said that the chemicals are six phthalate esters, members of a group of so-called plasticisers which are added to polyvinyl chloride products to make them flexible, and that proposed production levels would involve 300 to 400 production workers, and up to 10,000 plastic goods workers.

The EPA's actions are based partly on the results of a study being carried out by the National Cancer Institute which seems to be proving that DEHP, a widely-used plasticiser with a similar chemical structure, can cause liver cancer in mice and rats.

According to the agency, the company proposing to manufacture the new phthalate esters had not been aware of the NCI studies. And in submitting the PMN, it provided no reports on safety studies, leading the EPA to assume that none had been carried out.

EPA Deputy Administrator Barbara Blum said last week that, before manufacture is allowed to proceed, the company must provide information about the potential carcinogenicity of the new chemicals.

The action is the strongest so far to have been taken by the Agency under the TSCA. This reflects feeling among officials that some chemical companies are being excessively reluctant to provide data.

In a recent letter to a Congressional Sub-committee, for example, Dr Stephen Jellinek, Assistant Administrator for Toxic Substances, wrote that the lack of adequate test information was contrary to congressional intent in passing the Act, and "contradicts industry's oft-expressed view

of how it conducts its premanufacture activities".

Under the provisions of TSCA, companies must submit all existing test data about the safety of a new chemical, but are not required to carry out any additional tests unless the EPA determines that the production of the chemical could pose an "unreasonable risk" or would be in particularly large quantities. Environmental groups have criticised the flexibility of this arrangement. They argue that the EPA could have been more aggressive.

"The EPA says that the Act does not give them authority to promulgate rules for tests. But we feel that the Act does give it the power to gather any information they feel is necessary," says Dr Karim Ahmed of the Natural Resources Defense Council (NRDC).

The NRDC has already successfully sued the EPA over delays in implementing another section of the Act, which requires it to take action on a priority list of potentially dangerous chemicals drawn up by an interagency committee.

The Agency had argued that a 12-month time limit set by the Act required it merely to publish a progress report. However, three months ago a district judge in New York upheld the NRDC's contention that the actions themselves had to be carried out within this time. He said the 28 months which had elapsed since the priority list was published, and during which the EPA had taken no action against any of the listed chemicals, did not fulfil the congressional requirement.

NRDC members claim that the court victory strengthens their argument that the EPA could be moving more firmly to implement the provisions of the TSCA. In particular, it is arguing that the Agency has the power to set guidelines for the type of safety test data required to be submitted with PMNs.

This would bring the US more in line with actions recommended by the European Economic Commission that before starting production of a new chemical, a company would have to provide a certain amount of data on its potential environmental and health effects, in this case the amount of data depending on the proposed level of production.

The NRDC is proposing a 'tiered' scale of tests, with short term tests — for example for mutagenicity or chronic toxicity — required for all chemicals, and additional tests for those which are more

likely to be dangerous.

This approach, however, is being resisted by the chemical industry. "You have to consider how each chemical is going to be used. To have a laundry list of tests is too simplistic", says Dr Geraldine Cox, Technical Director of the Chemical Manufacturers' Association, who says that the current arrangement allows companies to talk to the EPA on a "scientist to scientist" basis.

Last week's actions indicate that the agency intends to "prosecute vigorously" the PMN provisions, according to one official. Its apparent commitment to a more aggressive stance on chemical testing was illustrated two days after the phthalate esters announcement, when Ms Blum told several leading chemical manufacturers that new safety tests would have to be carried out on the herbicide 2,4-D.

Unlike 2,4,5-T, 2,4-D does not contain dioxin contaminants, and there is no direct evidence that it is a health hazard. However, because of the structural similarity between the two substances, the EPA is demanding that new studies be carried out to eliminate any suspicion that it might be dangerous. □

Record rise in federal R&D backing

FEDERAL support for university-based research and development increased by $610 million to a total of $3,958 million between 1977 and 1978, the largest net growth since records were started in the early 1960s and the largest percentage growth since 1972, according to figures released by the National Science Foundation. The largest part of this increase came from the National Institutes of Health, whose support for university research increased by $262 million. The 1978 figures represented an 8% real growth in funding over 1977.

The NSF statistics indicate that the majority of research support is concentrated in relatively few institutions. In 1963, when records were first compiled, 90% of federal R & D support went to the top 100 research universities. In 1978, the top 100 universities received 84% of all R & D funds, compared to only 56% of total federal funds to universities.

Top recipient was Johns Hopkins University, whose $196 million of federal support — largely the result of incorporating for the first time the Defense Department-sponsored Applied Physics Laboratory — put the university far ahead of the previous leader, the Massachusetts Institute of Technology. □

CO₂ could increase global tensions

A strong warning that, since the global build-up of atmospheric carbon dioxide will have varying climatic effects on different parts of the world, it could lead to increased tension between rich and poor nations, has come from a special committee of the Academy of Sciences.

In a report prepared for President Carter's Science Adviser, Dr Frank Press, the committee says that such a build-up will only be minimised by international agreement to reduce the use of fossil fuels and develop alternative energy sources. And in view of the potential divisiveness of the CO₂ issue, it recommends that "in the near term emphasis should be on research, with as low a political profile as possible."

The committee, which was chaired by Dr Thomas C Schelling, professor of political economy at Harvard University, was asked by Dr Press to look at the social and economic consequences of increased concentrations of atmospheric CO₂. Accepting the scientific consensus that such an increase is likely to take place, the committee concentrates on what it considers the most serious consequences, namely the relative distribution of the resultant gains and losses throughout the world.

It points out, for example, that developed countries with temperate climates are not only the largest consumers of fossil fuels, but may also benefit from the climatic effects, with raised temperatures and rates of photosynthesis leading to increased agricultural yields. Both the US and the USSR could benefit in this way.

In contrast, countries in subtropical arid zones could suffer a decline in rainfall and possible droughts with decreased food production and resultant shifts in population distribution — as well as potential demands for international compensation.

"It seems that climate change might well tend to make the already poor still poorer and increase the difference between North and South, rich and poor, developed and developing" says the committee.

Research on adaptive and preventive measures are, it says, "apparent and urgent" to help mitigate the consequences. For example it recommends efforts to improve the resilience of agriculture to climatic change. And in particular suggests that ways should begin to be explored of protecting low-lying land areas from the possible elevation of ocean levels due to the disintegration of the West Antarctic ice sheet.

Finally, responding to two recent reports in the scientific literature which suggest that the rate of carbon dioxide build-up may be an order of magnitude less than most scientists now fear — reports which have become the centre of fierce controversy in the climate research community — the committee says it agrees with the views of experts it consulted that "these are based on incomplete assessments that unrealistically omit important feedback processes." □

Exxon supports MIT research

BREAKING away from more conventional patterns of research funding, the Massachusetts Institute of Technology and Exxon Research and Engineering Company announced last week a ten-year agreement under which the company will provide up to $8 million to support basic research at the institute into combustion processes.

In return, the company — the research arm of Exxon Corporation — will receive royalty-free, non-exclusive licenses to any patents which MIT obtains on technology arising from the research and will share any royalties on technology licensed to third parties.

Areas of research to be supported by Exxon include the burning of coal, coal liquids, shale oil and heavy crude petroleum. According to Dr Ed David, President of ER&E, a prime objective of the agreement is to "help generate the scientific base for more efficient and more environmentally acceptable burning of high sulphur, high nitrogen, hydrogen deficient fossil fuels" of particular interest to utilities and industrial companies.

Under the terms of the agreement, all results of the research can be published openly. ER&E will select the research projects it is prepared to finance from a list proposed by MIT. And in addition to this, an additional 20% of the total will be made available by Exxon to MIT scientists to pursue their own combustion science research projects.

The two principal investigators at MIT will be Professor John P. Longwell, who joined the institute faculty in 1977 after a long research career with Exxon, and Professor Adel F. Sarofim. Initial research projects to be carried out under the agreement include studies of the relationship of flame hydrocarbon intermediates to surface deposits and hydrocarbon emissions; and the interaction of mineral matter with sulphur during coal combustion.

The agreement is, according to the university, "one of the largest and longest of its kind" and is the result of protracted negotiations between the two sides over terms. It cannot be terminated without two years notice from either side, and in the words of MIT president Dr Jerome Wiesner "provides the university with the certainty that these long-range research programmes will have the financial continuity and stability to ensure effective performance".

The novelty of the agreement lies in the

MIT: receiving industrial support for basic research

fact that whereas industrial support of applied research on university campuses is a common phenomenon, it is relatively unusual for a private company to sponsor more long-term, basic research.

This role has, at least in the post-war period, been conventionally assumed by the federal government, on the grounds that basic research is a common good. However, in recent months a number of industry executives — among which Ed David and other Exxon officials have been some of the more outspoken — have argued that the private sector should take on more responsibility for supporting 'goal-oriented' basic research carried out in universities, arguing that because of changing political, social and economic factors, government may not have the staying power or the style of management to meet industry's long-term needs.

Recently one Exxon official suggested that industry's share of support for basic university research should increase to 15% from its current level of about 3%. The MIT-Exxon agreement is one of the first steps in this direction.

David Dickson

Smallpox

Gone for good?

TODAY in Geneva, the World Health Organisation will officially declare smallpox eradicated from the Earth. It will be the culmination of an astonishingly successful 22-year programme by the WHO, which included, in the two years since the last endemic case was reported in Somalia, the unclaimed $1,000 reward offered for new cases reported (*below*). But could smallpox ever recur? **Peter Newmark** examines the evidence.

Only five years ago . . . a WHO worker interviewing a child with smallpox in Ethiopia.

THE WHO campaign to eradicate smallpox was launched in 1958, a year in which 250,000 cases of the disease were recorded. At first success was slow to come by. Even vaccination of 90% of the population of a country was sometimes found to leave a sufficient residuum of the virus for it to bounce back with a vengenance.

By 1967 the disease was still endemic, or in serious danger of being so, in 50 countries. The WHO therefore hatched and launched an intensified campaign of eradication.

By any reckoning, the success of that campaign was remarkable. Ten years and $300 million later the last case of endemic smallpox was recorded.

Two and a half years later, the WHO is convinced that smallpox has gone for ever. In coming to that conclusion the WHO has considered three possible routes of re-infection but deemed them to be most unlikely, if not impossible.

The first would be if the virus could lie dormant in smallpox scabs that have survived this long. But the WHO is satisfied that the virus quickly becomes harmless in scabs.

The second possible source of re-infection comes from the smallpox virus stocks that are being held in the seven WHO-approved and inspected laboratories. That possibility last became a reality in Birmingham, UK, in 1978 when one worker died and another became mildly ill. Since these were not endemic cases they did not count within the WHO's definition of the 'last' cases. They did however, lead the WHO to increase its biosafety requirements and inspections, and to speed up its policy of closing down as many smallpox laboratories as possible. In two years, it is hoped, there will be only four, but some will have to be maintained indefinitely because of the possibility, however remote, that the virus could reappear from some other source, necessitating a new programme of diagnosis and vaccination. WHO plans to keep in reserve sufficient freeze-dried vaccine for 200 million people.

Meanwhile research is continuing on the third conceivable route of reemergence, by mutation from monkeypox virus. That possibility was raised in 1978 by the publication in *Nature* of experiments carried out in the WHO-sponsored Research Institute of Virus Preparations in Moscow, under the direction of Dr S S Marennikova. These showed that both in the course of passage of monkeypox virus through hamsters, and in the pock appearing on chorioallantoic membranes infected with monkeypox, there sometimes emerged a virus that was indistinguishable from smallpox virus in laboratory tests.

That conclusion was controversial from the start because of the considerable differences between the smallpox and monkeypox virus; although both are members of the orthopoxvirus family, as is vaccinia virus from which smallpox vaccine is produced, monkeypox very rarely infects man and, when it does, appears not to be transmitted from person to person; in the laboratory every test, from its molecular characteristics to the colour of the pocks it produces, distinguishes it from smallpox. Whereas that does not preclude the possibility of mutation of monkeypox to smallpox virus, recent, as yet unpublished restriction enzyme analysis of the genome of twenty-one mutants newly derived from monkeypox show that, despite instances of major deletions and rearrangements of genes, all of the mutants were still recognizable as monkeypox virus, and none closely resembled smallpox virus. The laboratories responsible for this work (those of Prof. K R Dumbell, in St Mary's Hospital Medical School, London, and Dr J H Nakano at the Center for Disease Control, Atlanta, USA) have also analysed the genome of six of the mutants obtained from monkeypox in Moscow in 1978, and the two monkeypox stocks from which they were derived. And at the molecular level, restriction enzyme maps of the two viruses show that the differences between them are so considerable that as Dr Nakano told *Nature*: "it seems highly improbable that the smallpox virus could ever be derived from the monkeypox virus by mutation".

However, Dr Nakano's laboratory has also analysed the four smallpox-like viruses isolated in Moscow from white pock on chorioallantoic membranes infected with monkeypox. Each of these mutants was indistinguishable from smallpox virus, confirming Dr Marennikova's identification of them.

The current position therefore seems to be that whereas it has not been possible to reproduce Dr. Marennikova's derivation of smallpox virus from monkeypox virus, and the genomic differences between the two viruses make such an event highly improbable, yet the evidence is clear that the Russian mutants are indistinguishable from smallpox.

There are two possible explanations, both unpalatable in their own way. The first is that Dr. Marennikova's results were the result of contamination. Obviously that can never be ruled out, and one of her two original monkeypox virus strains does appear to show signs of contamination with smallpox virus; however, the other does not.

The other possible explanation, and much the more worrying one, is that, despite the improbability, monkeypox virus *can* mutate to smallpox virus. That possibility is described by WHO as "highly unlikely, but impossible to disprove". All it can do is to continue to sponsor research — and hope that today's declaration of smallpox eradication is the very last one. □
Cell culture

Fetal calf serum drought hits cell culture laboratories

CELL culture laboratories throughout the world have been hit by their own fuel crisis — a shortage of fetal calf serum, the magic component of the media in which many biologists grow their cells. Supply has become uncertain, and the price has escalated; in the UK it has doubled in the past year and is now pushing £100 a litre.

Scientists are now exploring alternative ways of growing cells. At the very least they are in for a lot of trial and error, and time consuming work, as cells are weaned off fetal calf serum. Some projects will have to be abandoned.

Changes in world agricultural policies and practices lie behind the shortage, says Mr Tom Coutts, the managing director of Gibco Europe Ltd., which with Flow Laboratories, is the main distributor of fetal calf serum in Europe. He believes the overall supply will be bad for one or two years but may ease in the long term.

Flow was unable to supply any fetal calf serum at the end of April, and the company described the shortage as "very, very serious". In late April Gibco wrote to customers saying "severe shortages" would affect supply "for the foreseeable future . . . it is in our customers' interest to take every possible step to reduce their dependence on this product". Both companies hope the short term situation will be boosted by the start in April of the serum collection season in Australia and New Zealand, Europe's main sources of supply.

Fetal calf serum is a by-product of the beef industry. It is extracted by cardiac puncture when a cow brought to market for slaughter is found to be pregnant. Mr Coutts traces the current shortage back three years when beef prices were low, cattle were slaughtered rather than raised for the meat market, and calves, which would have become today's breeding stock, were lost. Now beef prices have risen and calves are being reared. Also, the US has lifted beef import quotas against Australia, making it even more profitable for Australian farmers to keep their calves.

Fetal calf serum is widely used by research institutes, hospitals, and universities for medical research, and by pharmaceutical companies in drug production. Its application includes use in diagnostic procedures, cancer research, and virology.

In the past the serum has been freely available, with just the occasional minor problem of supply. It has also been relatively inexpensive and extremely effective, curiously for reasons not yet understood. Its widespread introduction during the 1960s meant an end to the practice of scientists undergoing a self-imposed 24-hour starvation and obtaining a pint of their own blood for use in the medium.

Dr John Birch of Searle Research and Development says that "a great mythology" surrounds fetal calf serum. Dr Eric Hall, an English scientist at Columbia University in New York, says: "Tissue culture work using fetal calf serum has got a bit out of hand. We have sloshed it around because it was cheap and available. Some work has been done just for fun. We need to rethink our priorities." Now many laboratories will have to stop using it.

The Imperial Cancer Research Fund (ICRF) in London, which has about 70 people in tissue culture work, replenishes its supplies monthly and is now receiving about half the fetal calf serum (75 litres a month) it needs to meet its planned research programme. ICRF scientists have been asked to halve the amount of serum they use in media, to 5%.

University departments simply do not have the money to keep paying for the serum. Small laboratories are faced with a dilemma: either they pay high prices with the knowledge that they can successfully grow their cells, or they gamble with cheaper sera which may not give the desired results.

Professor Sydney Shall of the Biochemistry Department at Sussex University suggests that the number of places able to do tissue culture work will decrease. "It's a grave issue," he says. His cell lines are sensitive human cultures such as brain cells and they need 10% fetal calf serum. His department is rethinking its research programme.

Dr Colin Arlett of the Medical Research Council's Cell Mutation Unit, at Sussex, can provide an example. He is growing fibroblasts from patients suffering from ataxia telangectasia, a genetic disease. These cells are difficult to grow even on fetal calf serum and "if it becomes completely unavailable, or the price prohibitive, work on these cells will have to cease."

Cell biologists in Europe are no longer given the luxury of testing batches of fetal calf serum before purchase. They have been told by distributors to take what they are given or look for another source. Without testing, there is no guarantee that a particular batch of serum will support adequate growth of the cells being used.

"At least we have a buffer compared with smaller laboratories," Mr William House, manager of research services at ICRF, said. "If a particular batch of fetal calf serum doesn't suit one person's cell lines, it can be used by someone else."

The attitudes and methods of biologists themselves may be contributing to the problem. Panic buying has occurred over the last 12 months says Mr Coutts. The demand is artificially high, fed by the rumours of the impending short supply. Unwillingness to try alternatives and over dependence on fetal calf serum may also be factors.

In searching for alternatives, the most popular solution is likely to be weaning the cells onto other sera. Indeed, some scientists claim that they predicted problems of supply of fetal calf serum and have successfully changed to other sera. Alternative sera are less costly and more readily available. However, there may also be some problems.

New born calf serum, asceptic calf serum, and horse serum will support the growth of some cells, although usually with poorer growth rates; and some primary cell lines may have an absolute requirement for fetal calf serum.

Another complicating factor is whether or not the properties of the cells will change. Once the cells are growing on other sera, partially completed projects face the possibility of a change in the cellular response to the treatment — such as irradiation or drugs — under investigation. Earlier experiments which used fetal calf serum may have to be repeated. Dr Hall has already reported such cellular changes in response to chemotherapeutic drugs.

Many scientists believe that the ideal solution to the dual problems of the supply of serum and the variability it causes in the growth of cells can be solved by the use of a totally defined or synthetic medium. Attempts over the last 20 years to identify the magic ingredient(s) in fetal calf serum have not been successful; the latest shortage may revive this work. Several cell lines already grow on a totally defined medium and the popularity of these cells is sure to increase.

A further question arising from the shortage is the effect it will have on the anti-vivisectionist movement which believes that biologists should turn to tissue culture in preference to research using animals. Legislation to encourage this development has been proposed in the UK and elsewhere in Europe. But biologists working with animals are unlikely to change to tissue culture if they see such problems with the supply of serum.   **Ian Anderson**

NEWS IN BRIEF

EEC funds 10 new solar energy projects

THE Commission of the European Communities approved last week grants to 10 new solar energy projects totalling 3 million EUA (1 EUA = £.665). The projects include an award of 53,000 EUA to K.U. Leuven of Belgium for an electric car using solar energy and nine awards to solar heating projects which include block central heating by solar power for 250 houses in Alpes-Maritime in France, solar heating of greenhouses in Italy, a West German project to study solar heating of swimming pools and a project for solar energy heating of phosphorising vats at a refrigerator production plant in Pordenone, Italy.

UK locates geothermal energy source

AN exploratory borehole at Marchwood, near Southampton has located a large deposit of water at a temperature of 70°C the Secretary of State announced in Parliament last week. The water was found at a depth of 5,600 feet and can be brought to the surface at a temperature of 65°C a drop of only 5°C. There is sufficient water in the well to heat about 1000 houses over a period of several decades. Pumps will be installed late this summer to bring the water to the surface and its mineral content is being assessed.

Geothermal energy has been in use in Hungary since the beginning of the 20th century and has found increasing uses in France to heat apartment blocks in the Paris suburbs. France plans to have half a million geothermally heated buildings by 1990 which will produce a 15% saving in running costs. The UK's £1.8 million

UK Seveso report issued

AN English translation of the 1978 Italian Parliamentary Commission report on the Seveso accident was published by the UK Health and Safety Executive last week. The Executive clearly feels that the Seveso accident involving the discharge from a chemical factory of some 250-500 grams of 2, 3, 7, 8-tetrachlorodibenzo-p-dioxin (dioxin) over a populated area was serious enough to warrant a report of the causes and consequences of the incident being made more widely available. But central to the concern over the health of the Seveso residents was the two week delay in ordering their evacuation from the dioxin-contaiminated area: on this point the report has been criticised as inaccurate. For a detailed discussion see *Nature* 22 February 1979, page 588.

Queen's Award to new, safe insecticide

A GROUP of UK scientists received a Queen's Award last week for their development of a class of highly active insecticides that have low mammalian toxicity. Chemists and biologists at the Rothamsted Experimental Station solved the problem of making synthetic pyrethroid compounds, known from the group's previous research to attack insect but not mammalian nervous systems, stable against exposure to sunlight. According to Paul Needham of the Rothamsted Station the compounds break-down rapidly in soil and residues are unlikely to accumulate to contaminate the environment. Three compounds of the new class of insecticides, permethrin, cypermethrin, and decamethrin, are sufficiently active to be used at dosages of an oder of magnitude less (10-200 g/ha) than that of most other insecticides (500-1500 g/ha). The pyrethroids are effective against lepidopterous larvae in cotton, timber, wool and stored products.

Collection of Yeast Cultures finds home

THE UK National Collection of Yeast Cultures, threatened by withdrawal of funds by two of its sponsors last January (*Nature*, 24 January page 325) will be moved to the Agricultural Research Council's Food Research Institute in Norwich before the end of the year. The Collection, consisting of 1,500 yeast strains widely

used throughout Europe was saved by a decision of the Advisory Board for the Research Councils to provide the money to move and maintain the collection. The ABRC will provide about £24,000 annually so that the Collection can carry out its central functions of maintaining and supplying fully characterised yeast cultures to industry, universities and schools as well as acting as a reference and information centre for identification and deposit of yeast cultures. The collection will continue to be housed in its present quarters, the Brewery Research Foundation, until the transfer is effected during the summer.

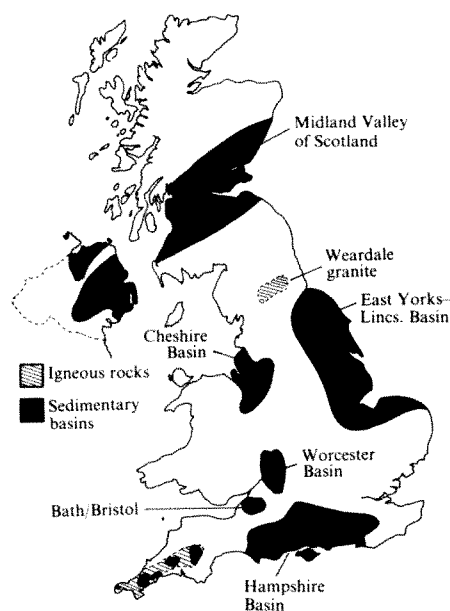
Research could help industry: Canadian report

INCREASED support for basic research in areas such as materials science and processing, vehicle control systems and battery electrochemistry could provide a long-term boost to the Canadian car industry, according to a report prepared by Arthur D Little of Canada Ltd for the Ministry of State for Science and Technology.

The report, prepared on parallel lines to an initiative (already under way) of the US government to stimulate research through projects jointly supported by federal and industry funding, lists a number of areas of "directed basic research opportunities" relevant to automotive technology which might be performed in universities or research institutes. "This kind of research is not directly intended to result in the design of new vehicles, engines, or components; it is meant to focus on achieving a fuller understanding of the physical and chemical processes underlying vehicle technology," the report says. But it adds that programmes of this nature, with a time horizon for commercialisation primarily in the 10 to 20 year range, must receive adequate government funding in order to be successful. "There are a large number of government sponsored research programmes in Canadian universities and government research centres that we believe are underfunded," the report says.

Errata

IN the leader of 17 April, page 583 David Howell was erroneously referred to as the UK opposition spokesman on energy. This should have been David Owen.

The letter from John Goddier in 24 April, page 658 was written in his capacity as Branch secretary of the Agricultural Research Council Branch Institution of Professional Civil Servants. It does not represent an official ARC view.


A birthday party with real rockets

Bulgaria is celebrating 1,300 years of nationhood next year, and scientific events are among the festivities. But as **Vera Rich** reports, the best birthday present the country could have would be a pollution-free water supply

LATER this month, Bulgaria will hold its second national conference on molecular biology — the first scientific event of the jubilee.

Dedicating a scientific congress to an event in the remote past may seem novel to western eyes, but it is merely one of a whole series of scientific events associated with the anniversary. In spite of its relatively small size and low science budget (about 1.3% of the GNP) Bulgaria is doing work at an international level in a number of fields, molecular biology included.

According to Dr Rumen Tsanev, of the Institute of Molecular Biology of the Bulgarian Academy of Sciences, work in molecular biology began some 10 years ago — before the Soviet decrees of 1974 which assigned priority to catching up in molecular biology and genetics. Lysenkoism, however, never really took hold in Bulgaria; there was some theoretical discussion of it in the 1950s but this was quickly over and, said Professor Tsanev, there was no persecution of people who did not accept it.

Bulgarian work on molecular biology has included: the discovery that the nucleosome consists of two sub-units; the formulation of mathematical models of cell differentiation; study of the role of histones in DNA transcription; and, most recently, two-dimensional electrophoresis studies of differences in the primary structure of nucleosomes. As for genetic engineering, "We feel it can only be developed as part of general molecular biology", Tsanev explained. "We started only last year, and at present we are simply trying to introduce methods of handling and mastering the techniques". Preparing too for genetic engineering, is Dr Basil Staikov of Bulgaria's unique "Rose Institute" at Kazanlak, a research station devoted to every aspect (from biochemistry to the mechanics of harvesting) of the Kasanlak roses whose essential oils play so significant a role in the Bulgarian economy. For the moment, however, Dr Staikov explained, Kazanlak has not the equipment for genetic engineering, and new varieties are still obtained by traditional cross-breeding methods; γ-irradiation experiments begun some four years ago, said Staikov, have so far given no definite results, although the general indications seem "promising".

Bulgaria is extremely proud of the scientific traditions it has established during the last century or so. The Academy of Sciences was founded in 1869. Bulgarian

Citizen-cosmonaut Ivanov. His space mission failed last year — but the scientific side of the programme was carried through.

scientists have been particularly active in solid state physics; but last year, according to Dr Milko Borisov, Director of the Academy's Joint Centre for Physics, the best results in Bulgarian physics came from work on liquid crystals, dielectric and flexielectric properties. Specialists from the Centre are cooperating with Polish and Italian teams on an "Atlas of liquid crystals" to be published by the Bulgarian Academy, probably in 1981.

International projects, naturally, cannot be dedicated to the Bulgarian jubilee. Nor, it seems, can the new astronomical observatory at Roehen, with its 200cm hyperbolic mirror with a Richey-Chretien-Coudé focus system. Much of the optical equipment came from Karl Zeiss (JENA) and when the observatory is formally opened later this year, it seems likely that it will be dedicated to DDR-Bulgarian friendship.

However, Bulgarian statehood will be celebrated in astrophysics. A special satellite Bulgaria–1300 will be launched by a Soviet rocket towards the end of the year. The experiments it will carry are, for the moment, a secret, but, according to Dr Kiril Serafimov, head of space research, Bulgaria is an active participant in all five sections of the "Interkosmos" programme — space physics, meteorology, communications, space biology/medicine, and remote geophysical sensing. Even before "Interkosmos" was set up as the official organisation for Comecon joint research, Bulgarian physicists assisted their Soviet colleagues in evaluating data from the "Elektron" probe — and later, from US satellites.

The Bulgarian public is still hopeful that their "space" celebrations might include the launch of a second Bulgarian cosmonaut, and with greater success than Georgi Ivanov, who with a Soviet crewmate, failed last year to link up with Salyut-6. But 20 of his scheduled experiments were carried out by the Soviet team on board including work with the Bulgarian Spektr-15 remote sensing camera (which weighs only 15.2kg but has 15 channels), the casting of an aluminium-hydrogen foam, work on epitaxial surfaces and crystal growth, and electrophoto-magnetic experiments on the aurora. Only the seven medical experiments scheduled for Ivanov had to be abandoned.

Perhaps the biggest scientific contribution to the jubilee will be the publication of Bulgaria's "Red Book" of endangered species. According to Professor Simeon Nedyalkov, of the Institute for the Coordination of Research for Environmental Conservation Bulgaria is, from a geobotanical point of view, a "melange" of boreal, mediterranean, pontic and Asia-minor species. Since the "technical revolution", especially around the country's new metallurgical plants, many species are threatened. There has been over-cutting of valuable timber; snowdrops have been depleted by the demands of the medical profession (they yield nivalin — an alkaloid used in the treatment of polio); and a well-intentioned attempt to step up trout production by introducing American varieties proved disastrous, for the newcomers failed to adapt to local plankton and became predators on the native trout.

Now, however, said Professor Nedyalkov, Bulgaria has a well established national monitoring system for all forms of air and water pollution, and in especially menaced areas, soil pollution also; and work is going forward on the resistance of plants to toxic elements.

Bulgaria's concern for the environment extends to the international level — not surprisingly, since its only sizeable river, the Danube, arrives too polluted even for irrigation. The existing Danube Commission covers only pollution from ships, and Bulgaria has been one of the most active of the riparian states in pressing for a Danube Convention to cover all aspects of monitoring and research into water quality and ecology. The preliminary text for a Convention has already been drafted and, said Dr Veselin Petrov of the Committee of Environmental Protection of the Council of Ministers, it is hoped that a final text will be signed this year. That would be the best 1300th birthday present Bulgaria could receive from the up-stream Danube countries. □

CORRESPONDENCE

Tumour surveillance in beige mice

SIR, — Since beige mice have been shown to have defective natural killer (NK) cells[1], several groups have reported recently in *Nature* on the presumed consequences — *viz.* poor immuno-surveillance for spontaneous tumours in mice[3,4] and men[4]. Padgett[5] reviewing Chediak-Higashi-syndrome of man, mink and cattle noted raised incidence of lymphoma. Beige mice are the murine equivalent. The gene, *bg^J*, was long ago obtained from the Jackson Laboratory on its C57 BL background and in this laboratory crossed onto a $(C_3H \times 101)F_1$ background and maintained thus. Neither of these Harwell strains nor the F_1 is noted for natural lymphoma. After the reported NK defect in C57 BL *bg bg*, 40 Harwell beige mice were set aside for life-time study. Others had been used for determining the origin of the osteoclast from the haematopoietic stem cell[6,7] during which electron microscopy studies of their bones had revealed C type virus, often in substantial numbers, in young mice. Of the 40 mice, now aged 15-18 months, 11 (27%) have died or been killed with a variety of disseminated lymphomas. The remainder suffer from ataxia noted around the age of one year and currently under investigation.

What should be called a lectin?

SIR, — During the past decade, interest in lectins (also referred to as agglutinins, phytohemagglutinins, phytoagglutinins and protectins) has increased enormously. The term lectin has frequently been used to describe substances which differ markedly from those classically considered lectins, that is plant seed carbohydrate binding proteins. Nevertheless, the discovery of lectin-like substances in widely diverse sources (bacteria, fungi, fish sera, snails, *etc*) appears to warrant an expansion of the term. For the sake of clarity we would suggest the following definition of "lectin".

A lectin[1] (from the Latin *legere*: to chose) is a sugar-binding protein or glycoprotein of non-immune origin which agglutinates cells and/or precipitates glycoconjugates.
● Lectins bear at least two sugar-binding sites, agglutinate animal and plant cells (most commonly erythrocytes, unmodified or enzyme-treated) and/or precipitate polysaccharides, glycoproteins and glycolipids.
● The specificity of a lectin is usuallly defined in terms of the mono-saccharide(s) or simple oligosaccharides that inhibit lectin-induced agglutination (or precipitation or aggregation) reactions.

● Although first discovered in plants, lectins also have been found in many organisms from bacteria to mammals. A lectin may be soluble in biological fluids (eg concanavalin A) or membrane-bound (eg rabbit or rat liver lectins).
● There are several other types of sugar-binding proteins including sugar specific enzymes (glycosidases, glycosyltransferases, glycosylkinases, glycosylpermeases, glycosylepimerases . . .), transport proteins, hormones (thyroid-stimulating hormone, follicle-stimulating hormone, . . .) and toxins (ricin, abrin, modeccin . . .), etc.

Under some conditions, sugar-specific enzymes with multiple combining sites agglutinate cells (and/or precipitate glycoconjugates) and so act as a lectin.

In spite of similarities to true lectins from the same source, toxins — which bear only one sugar-binding site — should not be called lectins since they do not agglutinate cells or precipitate glycoconjugates.

Thought for lowly locusts

SIR, — We were surprised, nay disappointed by the conclusion to your article (24 April, page 659) entitled 'Pores for thought', namely "There is every reason to believe . . . and will be followed by those of channels induced by a variety of neurotransmitters'. May we remind you that *Nature* published a paper last year entitled 'Single glutamate activated channels on locust muscle' (**278**, 643; 1979). Are we to believe that glutamate is not a serious contender as a transmitter? Perhaps the lowly status of locusts precludes them from serious consideration by Acting Editors of eminent journals.

Amanda and the scientists: a verse on syntax

SIR, — The following verses are intended to both amuse and instruct your readers, many of whom, judged by their contributions to your pages, are guilty of faults of syntax:

"Papa," said Amanda, "I want to know what
These scientists mean when they write:
'The dye was identified using a plot
Of *E* against wavelength of light.'

"Or here: 'The bacilli were easily seen
When using high magnification

And judging by leucocytes found in the spleen
They had caused an acute inflammation.'

"And in *Astronom. Rev.* I read: 'Bearing in mind
The value ascribed to log *g*
Circinus X-1 is now better defined
As a neutron low-mass binary.'

"But can germs use a microscope, dyestuffs a plot?
Are bacilli with judgement endowed?
Is it logs on the mind that makes neutron stars hot?
I protest that my mind's in a cloud."

Said Papa, "Your confusion is natural enough
But in time you will find it amusing
To know you can always spot scientists' stuff
By this typical misuse of using.

"Misattached participles are constantly seen
In scientists' journals today
For scientists rarely can say what they mean
Or, in consequence, mean what they say.

"They treat with derision linguistic precision,
Their syntactical errors are massive
And chiefly because of the quaint superstition
That the Voice of true Science is passive.

"Still, think of the blessings by Science bestowed:
The quasars and antibiotics;
The strontium-90, the helical code,
Carcinogens, quarks and narcotics!"

"Oh I do!" said Amanda, "Yet since you've explained
That their writings need mental translation
To be understood, I conclude that, though trained,
Most scientists lack education."

"That remark," said Papa, "though quite frequently heard
No iota of difference will make:
They language and logic abuse undeterred
With a confidence nothing can shake.

"To a study of leptons or nebulous Crabs
Ne'ertheless you may one day aspire.
For a start go and visit the Veterinary labs
And admire what there is to admire."

"Yes I will!" said Amanda, and seizing her coat
Ran off to that innocent band
Who were busy improving Rebecca the goat
By transplanting her mammary gland.

Yours faithfully,
R.F. GLASCOCK
With acknowledgements to Belloc.
Reading, UK

Taxi illusion — explained

SIR, — Surely the explanation of the "taxi illusion" (24 April, page 658) is as follows:—

Suppose the taxi is travelling at speed *V*. The passenger, looking back through the rear windscreen sees objects along the road receding at speed *V* relative to the taxi.

Looking forward, he sees the reflected images of those objects, apparently moving forward at speed *V* relative to the taxi.

He sees the images against a background of real objects seen through the front windscreen moving towards the taxi at speed *V*.

The reflected images therefore appear to be passing the real objects at a speed 2*V*.

Yours faithfully,
J.P. FREEMAN

NEWS AND VIEWS

Icebergs: technology for the future

from Herbert E. Huppert

EVERY year some 5000 icebergs, totalling 10^{12} m^3 of ice, are calved from Antarctic glaciers and ice shelves. Each iceberg consists of approximately 10^8 tons of pure fresh water. It drifts for a number of years under the influence of the currents and the winds, gradually breaking up and melting into the Southern Ocean. Occasionally, icebergs drift as far as 30°S, and may influence regional climate as well as local weather. At the time of calving each iceberg has a flat top and vertical sides which plunge some 200m into the water. After several years they may be worn into very convoluted shapes as can be seen in the cover illustration.

A recent conference on The Use of Icebergs* was mainly devoted to discussions of the physical characteristics of icebergs, including the way they break and roll over, their melt-rate, and the feasibility of capturing icebergs and towing them to Australia, South Africa, California or Saudi Arabia, where they could be used as a supply of fresh water.

Icebergs break due to the flexural strains induced by ocean swell and differential melting. Breaking can be enormously enhanced by the presence of flaws such as the cracks and deep crevasses that are frequently found in ice shelves. P. Wadhams (Cambridge University) presented calculations for the elastic response of a perfect, two-dimensional ice sheet to a given swell-induced pressure distribution at the base of the ice. The results yielded the maximum strain as a function of the amplitude of swell and size of the ice, the ice fracturing when the strain exceeds a postulated breaking strain. His calculations suggest that large ice sheets will not be broken up in seas which can destroy smaller sheets. Only very large icebergs would thus be expected to remain intact as they drift into regions far from the Antarctic coast. This fits well with the

observations that few medium-sized icebergs are seen in these areas. O. Orheim (Norsk Polarinstitutt, Oslo) reported that the 1978/9 Norwegian Antarctic Research Expedition found very few crevasses at the base of the 24 tabular icebergs on which they landed. If this is generally true, it suggests that icebergs are calved from the ice shelf along every basal crevasse, although it is possible that the ice around each crevasse had melted since calving.

The processes of iceberg melting were surveyed by H. E. Huppert (Cambridge University), who argued that the base of an iceberg was likely to melt less than the vertical sides. Melting at the sides of an iceberg into an ocean of uniform density leads to a turbulent, entraining plume containing upwardly moving melt water mixed with oceanic salty water. In regions where the ocean is vertically stratified, the melt water largely flows out in a horizontal series of layers (Huppert & Turner, *Nature*, **271**, 46; 1978 and *J. Fluid Mech.*, in press). There was evidence of both forms of convection in measurements taken around a grounded iceberg in Conception Bay, Newfoundland by E. G. Josberger (Oregon State University). An experiment in which a block of ice 1m × 0.5m × 0.25m was melted into water at approximately 20°C and 35°/oo was described by D. S. Russell-Head (University of Melbourne). Under these conditions it appeared that the basal melt rate was comparable to that for the vertical walls. This is possibly due to melt water formed at the base being able to flow up the sides.

Calculations for the frequencies of oscillation of an iceberg of given shape, and the shapes which lead to instability and hence roll-over, were the subject of a number of presentations. J. F. Nye (University of Bristol) presented an analysis based on catastrophe theory. From Nye's results it can be inferred that if the melt-rate increases with increasing depth the iceberg remains stable and is unlikely to roll over. This melting pattern was noted in the experiments above but in the Antarctic the melt-rate may be sufficiently influenced by local variations

in temperature and current speed to alter the resultant geometrical shape. All the calculations neglected the induced motion in the water, although this has been found by naval architects to be important (J. N. Newman, *Marine Hydrodynamics*, M.I.T. Press).

A number of results are already available from the 1978/9 Norwegian Antarctic Research Expedition. This was one of the first expeditions to obtain field data from Antarctic icebergs rather than just ice shelves. South of about 66°S, the measured annual melting was less than a few centimeters. Measurements of the temperature of the upper 10m of the bergs indicated that the temperature rose above that of the –20°C of the ice shelf to –5°C and higher. The expedition employed a sidescanning sonar to determine the underwater shapes of icebergs and ice shelves. The most exciting result, reported by B. A Fossum (Continental Shelf Institute, Trondheim), is the discovery of an underwater ram of ice protruding more than 180m at a depth of 100m from the ice wall at Kapp Norvegia. This contrasts with the completely vertical face mapped at Blåenga which is less than 100km away.

Iceberg Transport International have carried out a number of scaled towing tests and some of the results were reported by F. Mauviel (Iceberg Transport International, Paris). The tests consisted of towing a wooden 1/100 scaled model of a tabular iceberg in Brienz Lake, Switzerland, and a steel 1/60 model in St. Malo Harbour, France. Propulsion was provided by outboard motors, or by sails, or by hauling on lines attached to a very large parachute drogue ahead of the model. The last means of propulsion appears to be the most efficient. Extrapolating from the test results, Mauviel estimated that a reasonable efficiency could be achieved by using two drogues of 10^5 m^2 to propel an

Herbert E. Huppert is in the Department of Applied Mathematics and Theoretical Physics, University of Cambridge.

iceberg through the water at a speed of 0.5 knots. The two drogues would be pulled alternately, operating, in principle, like the hands of a swimmer doing the Australian crawl. The drag acting on the models was noted to be a fairly strong function of shape and to be least for an "iceberg" whose maximum girth is amidships and whose vertical walls are tapered so that the bow and stern width are approximately 3/5 of the central width. It is envisaged that the next series of tests will involve an actual Arctic iceberg that is roughly 1/10 the size of an Antarctic berg.

A study by D. J. DeMarle (Rochester Institute of Technology, New York) focused on the feasibility of processing icebergs in Saldanha Bay, on the west coast of South Africa. The region has been listed as a future metropolitan growth area by the South African Department of

Environmental Planning. Instead of melting the iceberg on arrival, DeMarle proposed that it be mined using existing technology. A slurry of ice fragments and water would then be pumped ashore via an ocean pipeline. The operation might be powered by the waste heat of a nearby industrial complex, for which a large cold sink could help to increase efficiency.

M. W. Holdgate (Department of the Environment, UK) highlighted the audacious simplicity and social benefits of using icebergs as an inexhaustible source of water. However, such a scheme is not without dangers, not only because of accidents which could result from a stream of broken off icebergs being abandoned in shipping lanes but also because we have little idea of the environmental effects of moving icebergs around the world. □

of available SRS, so described because the bulk of the research over this period concentrated on material chemically released with the ionophore A23189, rather than the immunologically generated SRS-A.

In May 1979, at the international prostaglandin conference in Washington, Bengt Samuelsson of the Karakinska Institute in Stockholm, in collaboration with Borgeat, Hammarstrom and Murphy described the work which led to the characterization of the leukotriene (LT) structures LTA, LTB and LTC from a murine mastocytoma cell line and from rabbit polymorpho-nuclear leukocytes. LTA was shown to be 5.6 epoxyarachidonic acid, LTB a dihydroxy-arachidonic acid and LTC as 5 hydroxy 6 cysteinyl arachidonic acid. His suggested name derived from the leucocytes which release the material and the conjugated triene system of double bonds in the structure. These double bonds were also responsible for the chromophore at around 280 nm, an observation made by both Piper's and Parker's groups.

A relationship was suggested between this chemically released SRS, now to be known as leukotriene C, and SRS-A but the picture was not yet complete. At the end of 1979, and in early 1980 Samuelsson, in collaboration with the chemical group of Corey at Harvard, described LTC as glutathionyl hydroxy arachidonate. Comparison of the biological activities of the natural with totally synthesized material showed them to be identical. It should be stressed, however, that this natural material was chemically released and so could not be correctly called SRS-A. Also, early in 1980, Piper and Morris characterized an SRS chemically released from guinea pig lung as glycly-cysteinyl hydroxy arachidonate, differing from the LTC described by Corey and Samuelsson by a glutamic acid residue.

SRS-A and the leukotrienes

from W. Dawson

THE discovery of a new class of biologically active compounds is always exciting, even at the present time when knowledge is advancing so rapidly.

The leukotrienes are a new structural class deriving from arachidonic acid, a precursor which has already given us the prostaglandins, thromboxanes, prostacyclin and various hydroxy fatty acids. The systems from which the leukotrienes have been released and characterized are closely related to immediate hyper-sensitivity reactions and it has been proposed that SRS-A, slow reacting substance of anaphylaxis is a member of the leukotriene family.

Slow reacting substances (SRS) are so-called because of the characteristic slow contractile response they induce in smooth muscle preparations *in vitro*. The original SRS from lung tissue was described by Kellaway and Trethewie in 1940, being released from guinea pig lung by snake venom. In a series of papers in the early 1950's Brocklehurst isolated and characterized a similar substance released from guinea pig lung following anaphylactic challenge and named it SRS-A. He later identified a similar product released *in vitro* from human lung, derived from an asthmatic person in response to the specific allergen. This work clearly linked SRS-A with the long lasting bronchoconstriction experienced by asthmatics.

For the next 25 years many research groups attempted to identify the chemical structure of SRS-A, notably those of Brocklehurst himself in England and Austen with the late Robert Orange in the USA. Although advances were made, the structure remained elusive. Undoubtedly the extreme potency of SRS-A, the relatively small amounts of material available, and its unusual physico-chemical properties were the major causing slow progres of this research.

During the 1960's and early 1970's the prostaglandin (PG) family of structures were identified and their pharmacology described. It seemed natural that the analytical challenge of SRS-A should attract workers in the PG field and within a relatively short period of time publications from many research groups appeared in the literature. The independent work of Parker, Piper and Bach all suggested incorporation of radiolabelled arachidonate into SRS-A-like biological activity whilst two groups, at St. Louis and Lilly, showed incorporation of 35 sulphur. The Harvard group identified sulphur by spark emission spectroscopy in their SRS-A preparation and it seemed clear that it was only a matter of time before the structure was revealed.

During 1978 and early 1979, both Parker and Jakschik in St. Louis and Piper and Morris in London suggested various functional groupings which they felt were present in the molecule. In particular, the chromophore at 278-280 nm seemed a key to the purification of the minute amounts

In this issue of *Nature* (p. 104) Piper and Morris describe the first characterization of immunologically released SRS-A from guinea pig lung, achieved with a novel mass spectrometric procedure, and show that it is identical with the chemically released material released from this tissue.

Developments in this field are so rapid, however, that Samuelsson described the same compound at the Winter Prostaglandin Conference in Snowbird, Utah this April and showed that it was formed from leukotriene C by the enzyme A-glutamyltranspeptidase. He named it leukotriene D and described, in collaboration with a number of his colleagues, various aspects of the pharmacology of the leukotriene compounds: A, B, C and D.

It is pertinent to note that the majority of the data presented by the various groups is chemical in nature and the biological activity of these compounds will need to be clearly defined. No doubt in the ensuing months biological flesh will be put on these exciting chemical bones. □

W. Dawson is in the Lilly Research Centre Ltd., Windlesham, UK.

Is the homing pigeon's map geomagnetic?

from Bruce R. Moore

RACING pigeons released six hundred miles from home often return within the day. Their remarkable performance reflects true navigation, not piloting or random search. The animals are known to obtain directional information from the sun, and appear to possess, in addition, a magnetic compass. Although the precise mechanism of magnetic detection remains unknown, two possible receptors have now been identified (see Presti & Pettigrew, this issue of *Nature*, p. 99). Moreover, there is evidence that the earth's field may provide not merely directional, but also positional, information: a compass, but also a map.

The pigeon's use of a solar compass has been shown in several ways but most dramatically in a demonstration in which the birds were made to fly, essentially, north, south, east or west by phase-shifting their diurnal rhythms (Schmidt-Koenig, *Cold Spr. Hrbr. Symp. Quant. Biol.* **25**, 389; 1960). Normal animals treat the direction of the noon sun as south and, when released, "home" properly. If, however, their diurnal rhythms have been advanced by six hours, they treat the sun's noon azimuth as west, and if retarded by six hours, as east; such animals fly 90° left or right of home. Others, phase-shifted by a full 12 hours, err by 180°. In each case the birds are seen to correct for the sun's apparent movement at an average rate near 15°/hour.

"Clock-shift" experiments such as these work, and should work, only when the sun is visible. When the sky is heavily overcast, experienced birds are still able to home, whatever the phase of their rhythms (Keeton, *Science* **165**, 922; 1969). Obviously, then, there is an another mechanism besides the solar compass. This alternative appears to be magnetic.

The seminal paper on magnetic effects was that of Keeton (*Proc. natn. Acad. Sci. U.S.A.* **68**, 102; 1971) which showed that fastening strong magnets to the backs of experienced birds interfered with their orientation on sunless days. Three years later, Keeton *et al.* (*J. comp. Physiol. A.* **95**, 95; 1974) found that pigeons' bearings were affected by even minor fluctuations in the geomagnetic field. Changes of less than one milligauss — a five-hundredth of the natural field — were accompanied by appreciable anti-clockwise deflections of the birds' initial flight bearings. This was confirmed by Larkin and Keeton (*J. comp. Physiol. A.* **110**, 227; 1976); and again by Richardson (*Ibis* **118**, 309; 1976) in observation of diurnal migrants. Again with migrants, Wiltschko and Wiltschko (*Science* **176**, 62; 1972) appeared to show that the magnetic receptor, whatever and wherever it might be, reacted not simply to

the horizontal component of the earth's field but, rather, to its direction of inclination; Walcott and Green (*Science* **184**, 180; 1974) reported consonant findings with pigeons.

The nature and location of the magnetic receptor remained a mystery, but the literature provided several clues: the experiments of Keeton and of Walcott and Green suggested that the organ should first be sought in the animals' heads or necks; additionally, it was known that organisms as diverse as bacteria (Blakemore, *Science* **190**, 377; 1975), molluscs (Lowenstam, *Science* **156**, 1373; 1967) and arthropods (Gould *et al.*, *Science* **201**, 1026; 1978) are able to synthesize particles of lodestone — or, more properly, magnetite.

The same substance has now been detected in the heads and necks of homing pigeons (Walcott *et al.*, *Science* **205**, 1027; 1979; Presti & Pettigrew, this issue of *Nature*, p. 99).

Walcott *et al.* analysed more than twenty pigeon specimens and found, in each, a single small pocket of magnetic material, just beneath the skull. Electron-probe and X-ray analysis, colour, and a Curie point near 580°C, collectively revealed the material as Fe_3O_4, magnetite. Electron-microscopic analysis showed numerous small elongated particles, of a size and shape which would act as elemental magnets, i.e., as single domains (Butler & Banerjee, *J. geophys. Res.* **80**, 4049; 1975). The tissue contained perhaps 10^7 such particles. It also contained nerve fibres, although of unspecified origin.

Presti and Pettigrew did not encounter this structure in any of nineteen pigeon specimens which they examined. The reasons for the discrepancy are not entirely clear, but it should be noted that both groups of investigators were obliged to work with cumbersome glass dissecting tools, and that, perhaps as a consequence of this, the anatomic location of the structure had not been specified.

Presti and Pettigrew did, however, discover other deposits of magnetite. These were in neck muscle and surrounding tissue in both homing and feral pigeons, and various species of migrants. The authors suggest a functional connection with sensitive stretch detectors.

The physical basis of the suggested mechanism is quite straightforward. Magnetite is composed of ferrous (FeO) and ferric (Fe_2O_3) oxides, and thus contains three Fe ions. The electron spin of one of

these is characteristically opposite to the others, giving a net magnetic effect. Magnetic poles exist in pairs, and in the Earth's weak, locally-uniform field, dipoles twist toward alignment. Whether the resultant torque could be detected, even by spindle receptors, in the *Sturm-und-Drang* of flight might perhaps be debated. But, as with the subcranial structures of Walcott *et al.*, the ultimate test of the proposed receptor will be electrophysiological.

When the avian magnetic receptor is finally and unequivocally demonstrated, a fundamental functional question may remain. Does the receptor supply a compass alone, or also, perhaps, a "map"? This possibility was touched upon by a number of speakers at a recent symposium*.

The Earth's field contains positional, as well as directional, information. Between the magnetic pole and equator, the field's strength and inclination, and therefore the strengths of its horizontal and vertical components, change systematically. Any two of these measures, or any one of them plus declination, could be used to form a bicoordinate map — an imperfect map in many ways, marred by anomalies and ambiguities, and subject to distortion by magnetic storms, but nonetheless, perhaps, serviceable (Talkington, *A.A.A.S.*, 1964).

In fact, birds released near magnetic anomalies do behave as if their "maps" have been affected (Walcott in *Animal migration, navigation, and homing*, Springer-Verlag, 1978). The related effects of magnetic storms have been known for decades (Thauzies, *Arch. de Psychol.* **9**, 66; 1910), but have not received sufficient attention. The most informative data here are those of Keeton *et al.* (op. cit.) showing anti-clockwise deflection of pigeons' initial flight bearings. Storms of apparent magnitude (K_{FR}) 3-5 caused deflections of 13° at one release site and 36° at another. One might suppose that the birds' compasses had been deflected, but field rotations in magnetic storms do not reach 36°, or 13°, or even 1°. The effect on the birds was clearly magnetic (see Larkin & Keeton, *J. comp. physiol. A.* **110**, 227; 1976), but could not have involved any obvious sort of compass.

A more plausible explanation would be that the storms had somehow affected the animals' sense of location. One release site was north and slightly west of the home loft, the other west and slightly south. In each case the animals reoriented as if they had been transported several tens of kilometers southwest of their true locations. At the times of release, and throughout the

preceding nights, the magnetic storms had changed local field strengths by, at most, a few parts per thousand. The birds' sensitivity to these small changes was astonishing. The scale factors cannot be determined precisely from published data, but were of the order of 10°-40° rotation per milligauss. The birds reoriented as if the storms had produced magnetic fields (or

Bruce R. Moore is in the Department of Psychology, Dalhousie University, Halifax.

perceived fields) like those normally prevailing southwest of the actual release sites.

Many other "maps" have been proposed, based upon solar position or movement, stars, sounds, odours, coriolis forces, landmarks and inertial guidance. The data have not, to date, supported even the most plausible of these hypotheses. I think that, perhaps, the time has come to take seriously an earlier suggestion (Viguier, *Rev. Phil.* **14**, 1; 1882) that the pigeon's map is geomagnetic. ☐

Superfluorescence: macroscopic quantum fluctuations in the time domain

from Q.H.F. Vrehen, M.F.H. Schuurmans and D. Polder

THE process of spontaneous emission of radiation from a collection of excited atoms is commonly called superfluorescence. Superfluorescence produces radiation pulses which have much larger amplitudes than those which one would obtain in normal incoherent atomic radiation processes. The phenomenon is intrinsically quantum mechanical because the decay of the entire excited system is initiated by a single spontaneous emission due to quantum fluctuations.

Spontaneous emission by excited atoms has been commonly viewed as a random process in which the stored energy is released in the natural life time τ_n of the excited state. However, in 1954 Dicke[1] predicted that under certain conditions the energy is released cooperatively and in a much shorter time $\tau_R \sim \tau_n/N$, where N is the number of excited atoms. Correspondingly, the emission intensity is proportional to N^2 instead of N as expected for random individual emission. Of course, such an N^2 intensity behavior is well-known from the coherent emission of driven electric dipoles. However, excited atoms have no dipole moment; classically the atoms would not even radiate. Nevertheless, the prediction is that cooperative behaviour develops in this system and leads to an emission intensity proportional to N^2 and an emission time proportional to τ_R/N — the phenomenon of superfluorescence (SF).

The first experimental observation of SF was made by Feld and collaborators [2] in 1973. Since then SF has been observed on a number of near-infrared, infrared and optical transitions (Ref. 3 and references therein). SF from a pencil shaped volume of active atoms has been studied systematically [3] in atomic cesium. The SF emission from the pencil goes mainly

Q.H.F. Vrehen, M.F.H. Schuurmans and D. Polder are in the Philips Research Laboratories, Eindhoven, Netherlands.

through its end-faces into two narrow solid angles $\Delta\Omega$. The emitted light pulse reaches a peak intensity proportional to N^2 at the so-called delay time $\tau_D \sim (\tau_R/4) (\ln N)^2$ where $\tau_R \equiv \tau_n/(N\Delta\Omega/4\pi)$. The emitted field behaves as a classical coherent field. It has a well-defined amplitude and phase: SF emission pulses from two different samples with slightly different SF transition frequencies produce beats [3]. When the atomic system is repeatedly raised to the same excited state by single shot pulse excitation, the emitted SF pulses show macroscopic fluctuations from shot to shot in properties such as delay time and shape. These fluctuations are of quantum-mechanical origin. Such experiments provide a unique opportunity to study macroscopic quantum fluctuations in the time domain. This phenomenon has recently attracted the attention of theorists and experimentalists [3-9].

The fluctuation behavior observed here may be compared with that of a needle initially placed upright in the gravitational field. In a gaseous atmosphere atoms will collide with the needle, providing a stochastic force which turns the needle away from its upright position. With increasing polar angle θ, gravity will contribute more and more and eventually the trajectory of the needle becomes deterministic with a fixed azimuthal angle φ. When the needle is repeatedly put upright its trajectory is unpredictable as regards φ. The time it takes the needle to reach the horizontal position fluctuates from experiment to experiment. The fate of the needle is mainly determined by the unpredictable events in the early stage of the experiment.

The unpredictability of the path of the needle from one experiment to the other results from the incomplete knowledge of the system as regards the positions and velocities of the colliding atoms. In quantum mechanics a different kind of

incomplete knowledge arises. It is related to the Heisenberg uncertainty in the results of measurements on two non-commuting observables. Often this uncertainty may be accounted for classically by introducing fluctuations in the various quantities. SF is initiated by such quantum fluctuations. The initially excited atoms are in an energy eigenstate. The energy does not commute with the electric dipole moment and consequently the dipole moment is uncertain. The electromagnetic field is initially in the vacuum state, with no photons present, and in that state the electric field is uncertain. The initiation of SF requires a quantum-mechanical description. Early important contributions of this nature are due to Bonifacio and Lugiato[4]. Recently, Glauber and Haake[5] (GH) and the present authors[6] (PSV) have obtained analytical solutions for the early stage of SF evolution by linearizing the equations of motion and decoupling the forward and backward emission. In the GH work the SF starts from the quantum fluctuations describing the uncertainty in the initial dipole moment; such a description is particularly suited to the calculation of the electric field variables. In the PSV work the SF starts from the quantum fluctuations of the electro-magnetic field in vacuum; such a description is particularly useful for the calculation of the atomic variables. The two approaches have also been combined in one complete linear quantum theory[7]. Haake and collaborators[8] have extended the linear theory into the non-linear regime by assuming that the system evolution becomes already classical in the linear regime. They have numerically calculated single shot outputs.

In the above theories the various fluctuating quantities are expanded in plane wave modes passing through the pencil in all directions. The dominant gain of the modes in the solid angles $\Delta\Omega$ is used to describe the formation of two collective plane-wave-like dipole modes along the pencil axis. This collective, antenna type, behavior in the forward and the backward direction leads to the N^2 peak emission intensity and the characteristic emission time $\tau_R = \tau_n/(N\Delta\Omega/4\pi)$.

The collective behavior of the atomic system is very similar to the behavior of the needle mentioned earlier. Different single shot SF outputs correspond to different trajectories of the needle after it has been put upright. The eventually deterministic behavior of the needle corresponds to the classical behavior of the SF single shot emission field; collective field and dipole modes eventually outgrow the noise in strength. The SF pulse has a fixed but unpredictable phase and its delay time fluctuates from shot to shot.

SF is particularly interesting because the quantum fluctuations reveal themselves in the time domain. The strength of the initiating quantum noise determines the average delay time. The stochastic properties are manifest in the delay time

fluctuations. Experiment[9] confirms the prediction of the linear theory[5-7] that the strength of the initiating quantum noise is such that, on average, SF is set off by the first photon emitted spontaneously in the solid angle $\Delta\Omega$. The relative standard deviation in the delay time of 12% at $N = 10^8$ atoms, as predicted by both the linear and the more complete nonlinear[8] theory, is in good agreement with preliminary measurements by one of us[3].

It is amazing indeed that such large fluctuations, quantum mechanical in origin, can be observed in nearly classical coherent pulses containing as many as 10^8 photons. □

Sun-weather effects

from R. Gareth Williams

IN a recent paper, Nastrom and Belmont (*J. geophys. Res.*, **85** C1, 443; 1980) have found an interesting correlation between the 11-year sunspot cycle and the upper troposphere and lower stratosphere. They have thoroughly and carefully analysed data from the Northern Hemisphere for a period covering 1949 to 1973, i.e., just over two solar cycles. Their results indicate that during the winters of this period, the average position and, to a lesser extent, the strength of the jet stream and the intensity of features such as the Siberian upper level trough, have a strong correlation with solar activity. It is not so much the statistical significance of the results which is surprising, but rather that in certain areas of the hemisphere 50% of the interannual variance is explained.

In order to consider the significance of these new findings, it is necessary first to review the general state of sun-weather effects. Despite almost 180 years of study, we have little evidence to support the hypothesis that solar activity significantly effects the troposphere. There is a plethora of statistical correlations, but many of these have been produced by over-filtering and selecting the data and the remainder have nearly all failed where the data sets have been extended in time. Also, there are no thoroughly evaluated mechanisms which explain how solar activity may affect either the climate or day-to-day weather. Indeed, there is a good reason why it is difficult to establish such a causal link; the energies associated with solar activity are very small when compared with tropospheric values (see, for example, Willis, *J. Atmos. Terr. Phys.*, **40**, 513; 1974). This means that any proposed mechanism will necessarily be indirect and complicated, and also that any statistical correlations, on their own, must be viewed with caution.

So, with this particular study by Nastrom and Belmont, although there is no doubt that the correlations are real (question marks raised by the authors over spatial coverage and the number of independent stations should only alter the details of the conclusions) the crucial, unanswered question is: 'Are the correlations caused by the changes in solar activity?'. The authors suggest that their findings may eventually be explained in terms of a direct solar effect on the stratosphere/mesosphere which, in turn, could modulate the upward propagation of tropospheric energy. There is clear theoretical and experimental evidence for the August 4th, 1972 solar proton event affecting stratospheric ozone. However, relationships between the solar cycle and ozone are somewhat controversial and thought at best to be small (< 1%) (Dutsch *J. Atmos. Terr. Phys.* **41**, 771; 1979). Correlations between other stratospheric parameters and the solar cycle are similarly not yet fully accepted and are generally based on short time series. The authors refer to the atmospheric model of Bates (*Quart. J. R. Met. Soc.*, **103**, 397; 1977)

R. Gareth Williams is in the Atmospheric Physics Group, Imperial College of Science and Technology, London.

which had a troposphere that was very responsive to changes in the stratosphere. More recent work by Shutts (*Quart. J. R. Met. Soc.*, **104**, 331; 1978) shows that this sensitivity is model dependent. Both studies use linearised equations. Nastrom and Belmont cannot indicate which aspect of the solar output is thought to be causing their correlations, so we do not know where in the atmosphere any proposed mechanism should start.

If we jump the gun (by quite probably at least a decade) and assume that these correlations are solar induced, well understood physically and that these upper tropospheric effects manifest themselves at the surface, then it is appropriate to consider what their impact on climate forecasting might be. Since 11-year trends in seasonal averages have been analysed, there will be no effect on day-to-day weather forecasts, nor on the 'long range' forecasts produced a month or so in advance. However, in localised regions of the globe it might become possible, for example, to forecast a run of 2 or 3 years with, on the average, cold winters. Such forecasts could, of course, have enormous economic impact. The drawback is that it is also necessary to be able to predict solar activity!

In conclusion, it seems unlikely that this present study will, on its own, alter the opinions of most meteorologists who view sun-weather effects with extreme scepticism. Only some very solid physics will do that and much theoretical work, coupled with further data analysis, will be needed to provide such firm footing. Even though it is free of the criticisms levelled at so many previous studies in this field, this paper will undoubtedly suffer, rightly or wrongly, from so many past correlations which were later found to be invalid. □

100 years ago

A Parisian speculator has inaugurated the aëronautical season by a private ascent on April 25 at La Villette gasworks. The baloon, of only 300 cubic meters capacity, bore one aëronaut, with 30 kilograms of handbills, which were distributed all over Paris. The wind being slight, with a favourable direction, thousands of these prospectuses were picked up by street passengers and largely read. The whole expense of the aërial expedition, gas and everything, did not exceed 10*l*. sterling.

The French Minister of Fine Arts has entered into an agreement with the Jablochkoff Electric Light Company to light the palace during the whole of the two months devoted to the exhibition. The number of lights fed by the machinery is about 400, and the motive power regarded at about 320 horses. The inauguration was to take place on May 1, and a large crowd had congregated to witness the process. But the crank of one of the principal engines broke, and it was necessary to postpone the opening for a few days. In spite of the growing opposition of the friends of the gas company, M. Garnier, the architect of the Paris Opera, will establish a trial of the principal electrical burners, to decide which is the more really fit for use in the house.

We learn from Catania, under date April 26, that the inhabitants were apprehending an eruption of Etna. An immense cloud of smoke has been observed.

A contemporary gives the following method of illustrating the indestructibility of matter: — Two sealed glass tubes of equal weight, one of them containing oxygen and a little powdered charcoal, are prepared. The charcoal may be caused to burn away completely by heating it by means of a small flame. On placing the two tubes on a balance it will be seen that there has been no variation in weight.

The emergence of Man

from Glyn Issac

ON March 12th the Royal Society and the British Academy convened a two day meeting to consider "The Emergence of Man". The central problem, presented by the chairman J. Z. Young, was to identify the kinds and timing of changes that led to human characteristics and the evolutionary pressures that produced them. The conference was characterized by the diversity of the methods being used to tackle these problems, contributions coming not only from paleontologists and anatomists but also from biochemists, immunologists, archaeologists and social psychologists.

Garniss Curtis (University of California, Berkeley) summarised geochronological information on the dates of important anatomical changes. In particular, evidence from fossils and footprints now demonstrates that bipedal locomotion was adopted between 3 and 4 million years ago. The age of the oldest fossils that show significant brain enlargement and which are classified into a species of the genus *Homo* has been the subject of controversy. A large series of new potassium-argon and fission track dates now all show that Koobi Fora early *Homo* specimens, including skull 1470, are close in age to the Olduvai Bed I *Homo habilis* fossils, that is between 1.7 and 2.0 million years in age. (*Nature* **283**: 368; 1980).

Elwin Simons (Duke University) reviewed information from fossils of the forerunners of bipedal hominids. Formerly the *Ramapithecus* specimens from the Siwaliks and from Kenya have seemed the most likely fossil ancestors of man. Simons showed that while this is still possible a spate of discoveries of fossils of *Ramapithecus*-like creatures in different parts of Eurasia complicates interpretations. These new finds from Greece, Hungary, Turkey and China indicate wider geographic range and more diversity than had been expected. Further study and the recovery of more associated postcranial material is needed before the phylogenetic relationships of the various forms can be regarded as settled. The oldest securely dated, substantial sample of early hominid skeletal reamins are the 3 to 3½ million year old fossils from the Afar in Ethiopia. Russel Tuttle (University of Chicago) reported briefly on features of the Afar hand and foot bones. He indicated that in spite of numerous primitive and ape-like characteristics there was evidence of

Glyn Isaac is in the Department of Anthropology, University of California, Berkeley.

anatomical shifts in the human direction. He was confident that the hands could have made and used tools and he showed that even ape hands have considerable ability in this regard.

J. Lowenstein (University of California, San Francisco) reported on some entirely new research which could have far reaching effects in the testing of phylogenetic hypotheses. He succeeded in extracting small samples of collagen, albumin and transferrin from fossils, and using the techniques of radio-immuno-assay he has succeeded in measuring immunological differences between the fossil proteins and living organisms. A series of tests, including on forms such as fossil mammoths, fossil bison and various marsupials have indicated the taxonomic reliability of the method. Clearly, when determinations have been made for *Ramapithecus* the results could help to settle the long-standing controversy over the date of divergence between apes and hominids.

The meeting circled rather warily round its central challenge — the evolution of the human brain and its relation to human abilities. R. E. Passingham (Oxford University) reported on new experimental work that explored the function of Broca's area. It seems likely that the area does not control sound production itself but rather the way in which sounds are assembled into sequences. Chimpanzees may have no need for such an area because their natural calls are not made up by varying the sequential order of elementary units. It was suggested that the development of such centres, where intricate sequences of motor control impulses are sent to a central organ, is accompanied by the development of dominance by one of the cerebral hemispheres. The localisation of motor control over human language in one hemisphere is paralleled by similar neural mechanisms in song birds and Passingham predicted that lateralisation might also be found in 'singing' cetaceans. The reason for lateralisation may be simply be to avoid interference from two controlling centres.

Ralph Holloway (Columbia University, New York) reported on the development of new techniques for establishing quantitative models of the shapes of human and hominid cranial endocasts. Not only have several hominid taxa turned out to be distinguishable from each other but some brain regions where differences are strongly represented; notably the lower parietal lobule, the anterior occipital zone and the dorsoanterior region of the frontal lobe, have been identified. The integration of this kind of research with information on brain function is clearly of importance.

Tool making and archaeology were also explored as sources of evidence regarding developments in brain function. Tobias pointed out that the transition to bipedal locomotion and the acquisition of enhanced manipulative abilities occurred long before the fossil record gave any indications of major changes in brain form

and size. Previously he had advocated tools as the crucial innovation, now he suggests instead that about 2 million years ago a situation arose in which biological and cultural evolution were in a positive reciprocal feedback relationship. In this "autocatalytic system", speech, along with tools, was a crucial component.

A somewhat different view was presented by Glyn Isaac (University of California, Berkeley). He suggested that the early representatives of the genus *Homo*, who between 1-1/2 to 2 million years ago formed the oldest known archaeological sites at the Omo, Olduvai, Koobi Fora and elsewhere, were non-taking, non-human hominids. The formation at that time of clusters of artefacts and of broken up bones does, however, encourage the hypothesis that the hominids had a social system involving food-sharing. This system could in turn have created novel selection pressures towards the development of language.

Further archaeological evidence was reported by Peter Jones (Oxford University). In experiments at Olduvai he made stone tools similar to those found at various Acheulian sites, in each case using the correct local raw material. The raw material has a strong influence on the finished form of the tool; this may well raise problems for our understanding of the development of tool making.

A new approach which may allow us to determine the diet and nutrition of early man was described by Alan Walker (John Hopkins University, Baltimore). Scanning electron microscopy of the occlusal surfaces of cheek teeth allows us, at least, to clearly state what early man was not eating. The early hominid species were not feeding either on grass (including grass seed heads) nor were they crunching bones in their jaws. The wear and polish found on early hominid teeth is comparable to that found on primates and other forms which feed on fruits and soft leaves. Biochemical studies also suggest that the robust australopithecines were not eating foods that required a different pattern of mastication from that of the gracile forms but simply had to process more food per jaw movement.

A dramatic find was described by Mary Leakey. A trail of footprints discovered at Laetoli in Tanzania has been shown to date to between 3-1/2 and 4 million years ago. Leakey believes that the trail belongs to a phase when human ancestors had become upright bipeds with their hands free of locomotor function but when involvement in stone tool making had not yet begun.

The meeting clearly brought out a variety of new approaches. However, such important problems as the circumstances surrounding the adoption of bipedal locomotion, the possible role of dietary shifts in guiding human evolution and the nature of selection pressures favouring brain development, all remain to be resolved. □

REVIEW ARTICLE

Calmodulin—an intracellular calcium receptor

Anthony R. Means & John R. Dedman

Department of Cell Biology, Baylor College of Medicine, Houston, Texas 77030

Calmodulin, a protein that binds calcium with high affinity and specificity, is structurally conserved and functionally preserved throughout the animal and plant kingdoms. It serves as an intracellular Ca^{2+}-receptor and mediates the Ca^{2+} regulation of cyclic nucleotide and glycogen metabolism, secretion, motility and Ca^{2+} transport. Calmodulin is also a dynamic component of the mitotic apparatus.

CALCIUM is involved in regulating a variety of cellular enzyme systems and in most types of cell motility[1-3]. The possibility that Ca^{2+} might not act in its free ionic form but rather requires the presence of a binding protein was first suggested by Meyer *et al.*[4] who reported that Ca^{2+} was necessary for the activity of muscle phosphorylase kinase. Bradham *et al.*[5] demonstrated the inhibition of bovine brain adenylate cyclase by EGTA and its reversal by Ca^{2+}. Kakiuchi *et al.*[6] and Cheung[7] independently discovered a heat-stable protein activator of brain cyclic nucleotide phosphodiesterase and 2 years later, Wolff and Siegel[8] purified a Ca^{2+}-binding protein from bovine brain. Weisenberg[9] found that neurotubules were destabilised in micromolar Ca^{2+} and Bond and Clough[10] found that a soluble protein fraction from haemolysates stimulated the activity of red blood cell Ca^{2+}-Mg^{2+}-ATPase. Pires *et al.*[11] discovered that a specific skeletal muscle myosin light chain kinase was dependent on Ca^{2+} for optimal activity.

It is now known that the same Ca^{2+}-binding protein acts as a mediator of Ca^{2+} regulation in each of these systems. Because it modulates enzyme activities in a Ca^{2+}-dependent manner, this Ca^{2+}-binding protein is now commonly known as calmodulin. As shown in Table 1, calmodulin regulates a number of fundamental cellular activities such as cyclic nucleotide and glycogen metabolism, intracellular motility (microtubules and microfilaments), and calcium transport as well as less defined Ca^{2+}-dependent protein kinases. Since we have been particularly interested in correlating the cellular and subcellular localisation of the protein with mechanistic studies carried out in defined biochemical systems, it has been necessary to determine the major physicochemical properties of the protein, to produce monospecific calmodulin antibodies, and to use these antibodies to answer a number of specific biological questions. In this review we will summarise our findings and how they integrate with the many other studies on calmodulin.

Physicochemical properties of calmodulin

Calmodulin exists as a monomer of molecular weight (MW) 17,000 and in the presence of Ca^{2+} resists denaturation (boiling, 8 M urea, 1% SDS)[12]. It is well established that calmodulin contains four calcium binding sites although reported affinity and specificity of the sites vary considerably. Binding of Ca^{2+} to any one of the four equivalent sites results in a conformational change. In this state over 50% of the molecule exists in an α-helical configuration. This conformational change is required in order for calmodulin to regulate any of the enzyme systems listed in Table 1. Data from our laboratory reveal that whereas phosphodiesterase activation can occur maximally with only one Ca^{2+} bound, the effect on microtubule depolymerisation requires all four sites to be filled. Thus it is possible that the

fractional occupancy of the Ca^{2+} binding sites may dictate the systems regulated by calmodulin and help to explain how this protein can be involved in such diverse biological processes.

Calmodulin from rat[13], cow[14] and the marine coelenterate *Renilla reniformis*[15] has been sequenced. It has 148 amino acid residues with no more than six conservative amino acid substitutions and only one of these in a calcium-binding domain. The protein is devoid of cysteine and tryptophan and contains a single histidine. The high ratio of phenylalanine to tyrosine (8:2) is reflected in the distinctive ultraviolet absorption profile and low molar extinction coefficient[12]; the high ratio of acidic to basic residues (2.7) accounts for the low isoelectric point (3.9)[12]. The most distinctive feature of the protein molecule is that the epsilon amino group of lysine 115 is post-transcriptionally trimethylated[16]. This modification preserves the positive charge and may influence the interaction of calmodulin with its multiple binding proteins, by analogy with the claim that trimethylation of yeast cytochrome *c* enhances its interaction with cytochrome oxidase[17].

Homology with troponin C

Many similarities exist between calmodulin and skeletal muscle troponin-C (TnC). These proteins cross-react in their respective biological systems[18-21]. Indeed, Kuo and Coffee[22] characterised a TnC-like protein from adrenal medulla that was subsequently shown to be calmodulin. The most obvious sequence difference between calmodulin and troponin C from rabbit skeletal muscle (STnC) or bovine cardiac muscle (CTnC) is that calmodulin is 7 or 8 amino acids shorter at the amino terminal region. This region is evolutionarily variable in the troponin C family[23,24], suggesting limited functional importance. In addition, TnC has three extra amino acids between positions 78 and 79 of calmodulin, and a single extra residue at the C-terminus. There is 45% direct homology between the two proteins, increasing to 78% for conservative replacements (substitution by functionally similar amino acids). The region of greatest homology is in the interior portion of the molecules (amino acids 30–77) where over 70% of the residues have exact identities. Other interesting features are the fact that all eight calmodulin phenylalanines and tyrosine-99 are invariant and the remaining tyrosine (residue 138) aligns with either a tyrosine or phenylalanine. Furthermore, 8 of the 11 calmodulin glycines seem to be invariant. It can be predicted that these glycines are located at sharp turns of the α-helical chain as is true for cytochrome *c*. Calmodulin, like the troponin C's[13,14,24] and parvalbumin[25], displays significant internal homology in and around the Ca^{2+}-binding sites. Sites I and III, and II and IV, contain high degrees of homology. These data would suggest that the Ca^{2+}-binding proteins evolved from a smaller ancestral precursor (which bound a single Ca^{2+}) by

gene duplication. Gene duplication is further suggested by the three residue deletion in calmodulin which occurs between binding domains II and III.

Antibody production

Calmodulin has proven to be a poor antigen, presumably because it is small, very acidic, and highly conserved in eukaryotic cells and tissues from diverse species. We have shown, however, that inoculation of animals (goat or sheep) with large quantities of homogenous calmodulin elicited a highly specific antibody[26,27]. Andersen *et al.*[28] also produced calmodulin antibody using alum-precipitated protein. More recently, Wallace and Cheung[29] elicited antibody to dinitrophenylated calmodulin.

Our antibody, purified by calmodulin-affinity chromatography specifically inhibits the activation of cyclic nucleotide phosphodiesterase by calmodulin[26] and specifically precipitates ^{125}I-labelled or ^{35}S-labelled calmodulin from a complex mixture of labelled protein[27].

The availability of antibody led to the development of a radioimmuno-assay (RIA) for calmodulin[27]. The immunoactivity of calmodulin in all tissues and cells is considerably greater than the activity determined by phosphodiesterase activation assay. This could be because calmodulin binding proteins in cell extracts compete with phosphodiesterase for Ca^{2+}-dependent binding, whereas the RIA is routinely performed in the presence of EGTA to prevent interference with calmodulin binding proteins. Alternatively there may be structural modifications (such as TML?) of calmodulin which prevent its interaction with some enzymes but allow association with others.

Regulation of calmodulin levels

The rate of synthesis and degradation of calmodulin in tissue culture or in tissue treated *in vivo* can be determined with an antibody precipitation technique[27]. Using this we have re-evaluated claims that there is more calmodulin in virally transformed cells than in normal counterparts not expressing the viral genome[30,31].

In both SV-3T3 and S-NRK cells, calmodulin levels were 2–3 times higher than in non-transformed counterparts and the rate of protein synthesis, including that of calmodulin, was also increased. However, whereas the rate of total protein degradation was markedly enhanced in the transformed cells, calmodulin degradation was only slightly altered. Since the doubling time of each cell type was reflected by the rate of total protein degradation, our results suggest that the degradation of calmodulin may be constitutive. Thus the elevated calmodulin levels in transformed cells are due to a general increase in protein synthesis that accompanies the transformed state.

Further evidence of the constitutive expression of calmodulin comes from experiments in which follicle-stimulating hormone (FSH) is injected into immature or hypophysectomised rats or added to culture media containing a homogeneous population of Sertoli cells[32]. Although FSH stimulates RNA and protein synthesis in Sertoli cells[33], calmodulin levels are unaltered. Similarly, although the expression of every other measured protein or enzyme in the chicken oviduct has been shown to be dependent on steroid hormones, calmodulin levels per cell remain constant regardless of the hormone environment. Collectively these data suggest that regulation of calmodulin-mediated enzymes is due to alterations in the net flux or distribution of Ca^{2+} rather than to changes in the cellular content of calmodulin.

Location of calmodulin in interphase cells

The purified, monospecific antibody has been used to localise calmodulin in a variety of animal cells by adopting the indirect immunofluorescence procedure described by Fuller *et al.*[34]. The cells were grown on sterile glass coverslips, fixed in formaldehyde and acetone, and then treated with the primary antibody: goat anti-calmodulin. After washing, the cells were exposed to a second antibody, rabbit anti-goat globulin tagged with fluorescein. Specificity of the immunofluorescence was tested by performing four controls: (1) use of preimmune goat γ-globulin fraction as the primary antibody; (2) use of the nonabsorbed affinity column material as the primary antibody; (3) pre-absorbance of the purified anti-calmodulin with a fivefold excess of homogeneous testis calmodulin; and (4) incubation of the second antibody without the primary (anti-calmodulin) antibody. The background fluorescence of the controls was quite low with only traces of nonspecific fluorescence. In interphase PtK_2 cells calmodulin was present throughout the cytoplasm yet appeared to be excluded from the nucleus[26,35]. Immunofluorescence also was observed in actin containing filaments extending, in some cases, across the entire length of the cell. A similar pattern of anti-calmodulin fluorescence was found in fibroblasts from humans, chick and *Xenopus* as well as rat Sertoli cells which are of epithelial origin[26].

The association of calmodulin with the actin containing filaments is presumably related to its role in the regulation of actomyosin ATPase activity in nonmuscle cells. Perry and associates[11] first described a calcium-dependent protein kinase in striated muscle that specifically phosphorylated the 20,000-MW light-chain (LC_{20}) of myosin. Subsequently, Yazawa and Yagi[36] purified this enzyme and discovered that it was composed of a catalytic subunit (MW ~100,000) and a calcium binding regulatory subunit (MW 20,000). This regulatory subunit was later identified by Yagi *et al.*[37] as calmodulin. Independently, Waisman *et al.*[38] described a similar skeletal muscle kinase that was regulated by calmodulin. Chick gizzard, as a form of smooth muscle, was subsequently studied with regard to the regulation of myosin ATPase activity. Again Dabrowska *et al.*[39] found that the myosin light chain kinase consisted of a catalytic and regulatory component, the latter being calmodulin. Even the myosin light chain kinase present in nonmuscle cells has been shown to be a calmodulin-dependent enzyme. This has been most carefully examined in blood platelets[39,40] and baby hamster kidney cells[18] in tissue culture. Taken together, these observations argue that calcium binds calmodulin and this complex activates the kinase to phosphorylate myosin (LC_{20}). This results in a conformational change to allow actin to come into contact with the myosin head group thus stimulating myosin ATPase activity. It has been demonstrated that such interaction results in increased tension development and presumably motility.

Localisation of calmodulin during mitosis

In mitotic cells, anti-calmodulin fluorescence was associated with the mitotic apparatus of 3T3 and PtK_2 cells[26] in all phases of mitosis (Fig. 1). Fluorescence was most intense at the spindle pole and projected towards the chromosome in a distribution
Fig. 1 Distribution of calmodulin during mitosis visualised by indirect immunofluorescence microscopy. Monolayers of rat kangaroo PtK_2 cells were plated on glass coverslips and prepared for immunofluorescent localisation of calmodulin as described by Welsh *et al.*[41]. Calmodulin antibody was raised in sheep and purified by affinity chromatography on calmodulin-Sepharose[26]. The fluorescein-labelled second antibody was rabbit anti-sheep. *a*, Prophase; *b*, prometaphase; *c*, metaphase; *d*, anaphase; *e*, late anaphase; *f*, telophase.

that gave the appearance of fibres. However, the pattern of calmodulin-specific fluorescence did not traverse the metaphase plate but instead terminated on or before reaching the chromosomes. Only in very late anaphase was calmodulin-specific fluorescence demonstrated transiently in the intrazonal region but again extremely close to the chromosomes. These data were independently confirmed by Andersen et al.[28] using an anti-calmodulin prepared in rabbits.

The distribution of calmodulin and tubulin was similar but not identical during mitosis[41]. Treatment of cells with colcemid disrupted the mitotic apparatus and caused a disappearance of specific fluorescence both for tubulin and for calmodulin. On the other hand, cytochalasin B, which under some circumstances dissociates microfilaments, had no effect on the mitotic apparatus. Similarly, no effect was noted on specific fluorescence patterns of tubulin or calmodulin. Nitrous oxide treatment causes the disorganisation of the mitotic spindle but does not result in disassembly of spindle microtubules. Treatment of Chinese hamster ovary cells with nitrous oxide disrupted spindle structure as seen with either tubulin or calmodulin specific fluorescence.

Finally, exposure of cells to low temperatures has been shown to effectively disrupt certain populations of microtubules in tissue culture. Intrazonal microtubules depolymerise when mitotic cells are incubated at 4 °C whereas the kinetochore-to-pole microtubule bundles are unaffected[42]. Experiments performed with anti-tubulin fluorescence confirmed previous studies in that the pole-to-pole microtubules were disrupted leaving only the cold stable pole-to-chromosome microtubules. On the other hand, such treatment did not affect the localisation of calmodulin. These results suggest that calmodulin might be preferentially associated with the chromosome-to-pole microtubules and thus, might be involved in the assembly/disassembly of microtubules that occurs during the movement of chromosomes from the metaphase plate to the spindle poles.

Brinkley and Cartwright[43] utilised electron microscopy to quantitate the number of microtubules present in serial sections of mitotic cells. When these data were compared to the localisation data for calmodulin, it was found that in all instances and in all phases of mitosis, the high concentrations of calmodulin were associated with low or nonexistent numbers of microtubules. Not only did this hold true in metaphase and early anaphase, but at very late anaphase, corresponding to the transient association with calmodulin on either side of the separating chromosomes, no microtubules were found in this region but were restricted to the portion of the cell corresponding to the developing cleavage furrow.

A role for calmodulin in assembly/disassembly of microtubules

It has long been known that microtubules are sensitive to calcium, although the concentration of calcium required for depolymerisation of microtubules has been somewhat controversial[9,44]. To determine whether calmodulin had any effect on microtubule polymerisation and might represent a protein involved in the assembly/disassembly processes, microtubule protein was isolated from rat brain by a modification of the temperature-dependent assembly/disassembly method described by Borisy et al.[45]. In order to control calcium concentrations, the calcium/EGTA buffer system described by Perrin and Sayce[46] and modified by Potter and Gergley[47] was used. Calmodulin alone (at 0.4 μM free calcium) or 11 μM of calcium alone caused only a slight reduction in the rate or degree of microtubule protein polymerisation[48]. However, the addition of 11 μM calcium combined with calmodulin abolished microtubule assembly. Thus, the calcium–calmodulin complex prevented the in vitro assembly of microtubule protein. In a complementary series of experiments, the calcium–calmodulin complex promoted complete disassembly of microtubules. Similar data have been reported by Kumagai and Nishida[49] using slightly different conditions and monitoring microtubule assembly/disassembly by viscometry.
Fig. 2 Effect of Ca^{2+}-calmodulin on microtubule assembly in lysed interphase 3T3 cells. Swiss mouse 3T3 cells were treated with colcemid to disrupt the cytoplasmic microtubule network and lysed with 0.05% Triton X-100. Phosphocellulose purified 6S tubulin was added to the lysed cells and allowed to incubate for 15 min at 37°C. Microtubules were visualised by indirect immunofluorescence microscopy using rabbit anti-tubulin[34]. This system was developed by B. R. Brinkley et al.[85]. a, Colcemid-treated cells. A few short microtubules can be seen at the cell periphery. Note the highly fluorescent spots that correspond to the centrosomal regions of the cell. b, Colcemid-treated cells following addition of 6S tubulin. Numerous long microtubules can be seen which have nucleated from the organising centres seen in (a). c, Colcemid-treated cells following incubation with 6S tubulin and 11 μM free Ca^{2+}. Again numerous long microtubules are evident. d, Colcemid-treated cells incubated with 6S tubulin, 11 μM Ca^{2+} and calmodulin. Microtubule assembly from the centrosomes has been prevented.

Collectively these immunofluorescence, biochemical and ultrastructural observations have led us to propose that calmodulin functions in mitosis to depolymerise the microtubules in the polar region, shortening the kinetochore-to-pole microtubules and allowing movement of chromosomes to the poles. However, it was unclear from our studies whether calmodulin acted directly on 6S tubulin, capped the assembly end of microtubules or interacted with the microtubule associated proteins. Therefore, we have established another system to investigate the potential role of calmodulin in polymerisation of microtubules.

In the interphase cell, microtubules arise from a single organising centre associated with the centrosome[50]. It seems likely, therefore, that if the cytoplasmic microtubule network could be dissociated, and the depolymerised tubulin removed from the cell, this organising centre could be used to nucleate assembly of microtubules. If cells were incubated in the absence of tubulin a fluorescent organising centre could be seen, but no microtubules could be found emanating from the centre (Fig. 2). Addition of 6S tubulin resulted in a large number of microtubules arising from each organising centre and lengths reached up to 35 μm. If calmodulin, in the absence of calcium alone or 11 μM was added, microtubule assembly proceeded without change (Fig. 2). However, if calcium and calmodulin were added together, microtubule assembly was completely prevented. Thus, this additional procedure also demonstrated a role for calmodulin in microtubule assembly/disassembly. Microtubules examined by electron microscopy were shown not to contain high molecular weight microtubule-associated proteins. This meant that if microtubule-associated proteins were important for assembly, they would have to have been present in the lysed cell system.

Immuno-electron microscopy using horseradish peroxidase-coupled Fab fragments of anti-calmodulin showed a specific reaction product in close proximity to the centrioles and to the kinetochores (Fig. 3). In addition, calmodulin was localised in smooth endoplasmic reticulum that was parallel to the microtubule bundles in the half spindle, and also in association with membrane vesicles and mitochondrial membranes. No calmodulin was found in direct association with the pole-to-pole
Fig. 3 Immunoelectron microscopic localisation of calmodulin. Calmodulin was localised in mitotic 3T3 cells and in rat cerebellar Purkinje cells using a calmodulin-specific Fab fragment coupled to horseradish peroxidase. The procedure was identical to that described by Lin *et al.*[86] and the experiments were performed in collaboration with Thomas Lin and B. R. Brinkley. *a*, A mitotic cell showing calmodulin reaction product around centrioles (triangle in upper left), kinetochores (triangle in middle), and some spindle microtubule bundles (×11,500). *b*, A cross-section of a centriole from another mitotic cell showing heavy deposition of reaction product around the microtubule areas. The microtubules are not evident since the sections were not counterstained. The centre of the centriole is unstained (×44,400). *d*, One Purkinje cell body from rat cerebellum showing calmodulin reaction product on free and bound ribosomes, plasma membrane, smooth endoplasmic reticulum and mitochondrial membranes (×11,000). Insert: high magnification from another area of the same cell. Dense reaction product is seen on membrane bound ribosomes and free polysomes (×25,000). *e*, High magnification of mitochondria from a neuronal dentrite. Calmodulin reaction product can be seen to decorate both outer and inner mitochondrial membranes (×30,000). *f*, A synapse from the cerebellar cortex showing heavy deposition of reaction product on a postsynaptic membrane (×46,000).

microtubules. These data support the information gained from the lysed cell system and suggest at least three possibilities for the role of calmodulin in the mitotic apparatus. First, calmodulin might directly regulate microtubule assembly/disassembly in the centrosomal regions. Second, calmodulin may regulate actomyosin. Herman and Pollard[51] have clearly demonstrated by immunofluorescence microscopy that the pattern of actin in the mitotic apparatus is very similar to what we have found for calmodulin. Unfortunately, the presence of myosin in the mitotic spindle is somewhat less clear. Nevertheless, because of the role of calmodulin in the regulation of actomyosin ATPase activity in interphase cells[18,26,35,37,39,40,52], this must be considered and is clearly a testable hypothesis. The third possibility is that calmodulin may be regulating membraneous calcium pumps. In almost all instances calmodulin was associated with various types of membranes in the mitotic cell. Since this protein, in association with calcium, has been shown to regulate the red cell calcium pump[53], the sarcoplasmic reticulum calcium pump[54] and the endoplasmic reticulum calcium pump, it is possible that one of the major roles of calmodulin in the mitotic apparatus is to regulate the concentration of calcium in the microenvironment of the spindle.

Additional roles for calmodulin

Multiple roles for calmodulin are suggested by its multiple localisation in all tissues, best illustrated in the rat cerebellum (Fig. 3). Calmodulin was concentrated in Purkinje and glial cell bodies where it was predominantly associated with free and bound ribosomes, the nuclear envelope, coated membranes of smooth and rough endoplasmic reticulum, mitochondrial and

plasma membranes[55]. Calmodulin was also found in the neuronal dendrites of the Purkinje cells, in which it coated the surface of smooth endoplasmic reticulum, small vesicles, and inner and outer mitochondrial membranes. In addition, granular calmodulin could be found in the central portion of the neuronal process. However, the neurotubules showed no specific association with calmodulin. The localisation in the neuronal process is in keeping with the suggestion by Iqbal and Ochs[56] that calmodulin may be important in mediating fast axonal transport. Calmodulin was also found by us, by Grab *et al.*[57] and by Wood *et al.*[58] on the inner surface of the postsynaptic membrane present in a variety of nervous system structures. Together these observations suggest that calmodulin is synthesised on both free and bound ribosomes and discharged into the cytosol. A large portion of this protein becomes associated with intracellular membranes. In addition, some calmodulin seems to be transported along the neuronal process to the postsynaptic membrane. At the postsynaptic membrane calmodulin may mediate the calcium effects on synaptic transmission and thus have a role in the release of neurotransmitters[59].

Satir and colleagues, in collaboration with our laboratory have revealed the presence of calmodulin in the basal bodies of cilia from *Paramecium*, *Tetrahymena* and the freshwater mussel *Elliptio*, and Jamieson *et al.* have shown that calmodulin is a constituent of the axonemal complex of cilia[60]. These data suggest that the effect of calcium on ciliary arrest might involve calmodulin. This possibility is supported by the localisation of calmodulin in mammalian sperm to the acrosome, in the midpiece associated with the fertilisation ridge and on both ends of the axonemal complex in the tail[61]. Since it seems that assembly of the axoneme can be controlled at both ends, calmodulin may have a role similar to that which it has in the mitotic apparatus during karyokinesis. In addition, the dynein of mammalian spermatozoa is similar to myosin in that it contains a Ca^{2+}-dependent ATPase[62]. It is, therefore, possible that calmodulin may modulate the dynein ATPase activity. In brief, calmodulin may be involved in promoting the attenuation of motility.

It has also been found to be associated with coated vesicles involved in receptor-mediated endocytosis. In collaboration with Linden and Roth[63], we have discovered that Ca^{2+}-calmodulin specifically binds to isolated coated vesicles with a dissociation constant of 10^{-8} M. The binding is calcium-dependent. In fact, half-maximal binding occurs at 2.4 μM free Ca^{2+} which is identical to the K_d of calmodulin for Ca^{2+} (ref. 12). The predominant calmodulin binding protein is clathrin. The biological function of calmodulin present in coated vesicles is unknown, but it is reasonable to suppose that it modulates the vesicle's calcium-dependent ATPase.

Table 1 Calmodulin-mediated processes

Process	Selected refs
Cyclic nucleotide metabolism	
Phosphodiesterase	6, 7, 71
Adenyl cyclase	71
Protein phosphorylation

Receptor-mediated calcium regulation

The mechanism of action of Ca^{2+} is different from that of other metal ions. Indeed, the role of Ca^{2+} seems to be more similar to the regulatory actions of cyclic nucleotides which produce multiple metabolic effects by binding to the regulatory subunits of cyclic AMP-dependent protein kinase and thereby activating the enzyme. The specificity of the cyclic nucleotide system of any cell is determined at two levels. The first is by the receptors (for hormones and so on, that elevate the intracellular content of cyclic AMP) the membrane is endowed with. The second is which substrate(s) for the protein kinase that the cell possesses. By analogy to cyclic AMP, it has been proposed that Ca^{2+} is an intracellular second messenger[1]. Continuing this analogy, calmodulin may be considered an intracellular receptor for Ca^{2+}. Evidence consistent with this is that (1) in non-muscle cells it represents the major high affinity Ca^{2+}-binding protein; the affinity for Ca^{2+} is approximately equal to the estimated intracellular free-Ca^{2+} concentration, suggesting that physiologically active cellular Ca^{2+} is calmodulin bound; (2) no alternate function (that is, enzymatic or structural) has been demonstrated; (3) it has been structurally conserved and functionally preserved throughout both animal and plant kingdoms, suggesting that it is involved in numerous cellular activities which require an invariant mediator; (4) it would be predicted that, in order to account for its many cellular activities, calmodulin would have multiple 'acceptor' proteins and a number of the major forms have been identified (Table 1). Many more probably exist. Studies by Grand and Perry have shown that each mammalian tissue possesses a distinct set of these proteins[64], through which the specificity of Ca^{2+} action is presumably determined. Amplification of a Ca^{2+} signal, like a cyclic AMP signal, can be accomplished through the activation of specific protein kinases which in turn may affect a number of additional enzyme activities. It is likely that the discovery of calmodulin and the developing understanding of how this protein is involved in the regulation of numerous calcium mediated events will provide a link in our understanding of the interaction of calcium and cyclic nucleotides in the control of cellular metabolism.

At the moment most of the data concerning calmodulin regulation must be considered as phenomenological. What is now required is a concerted effort to understand the chemical basis for each of calmodulin's actions. This will require isolation and purification of the enzyme systems regulated by this protein. Indeed, some success has already been achieved along these lines. Phosphodiesterase[65,66], myosin light chain kinase[37,52], phosphorylase kinase[67] and ATPase[68,69] have all been purified and calmodulin stimulated adenyl cyclase[70] is reported to have been partially purified. Even when one understands the interaction of calmodulin with these enzyme systems, it will be necessary to discover how hormones regulate the activity of calmodulin. Since this protein seems to be constituently synthesised it is likely that the activity is regulated by the concentration of available calcium.

Mutations which alter the function of the signal sequence of the maltose binding protein of *Escherichia coli*

Huges Bedouelle*§, Philip J. Bassford Jr†, Audree V. Fowler‡, Irving Zabin‡, Jon Beckwith† & Maurice Hofnung*§

The maltose binding protein of Escherichia coli *is secreted into the external periplasmic compartment of the cell by virtue of an amino-terminal signal sequence. Using DNA sequencing, we have determined the precise nature of mutations in the signal sequence which prevent the export of the maltose binding protein, causing it to accumulate in the cytoplasm in its precursor form. In most cases, the change of a single hydrophobic or uncharged amino acid to a charged amino acid within the signal sequence is sufficient to block the secretion process.*

MOST secreted proteins in both prokaryotic and eukaryotic cells are initially synthesised with an amino-terminal extension of some 15 to 30 amino acids which is subsequently excised. It has been proposed that this 'signal sequence' is responsible for initiating passage of the polypeptide through the membrane while it is still a nascent chain attached to the ribosome[1-3]. The exact mechanism by which this is accomplished, and the nature of the putative receptor in the membrane, are unknown. Among the different signal sequences thus far determined, there seems to be no significant primary sequence homology[4]. However, one feature common to all signal sequences is a central core of 9–24 predominantly hydrophobic amino acids. In most cases, this is preceded by one or more charged residues, usually lysine and/or arginine. One approach to defining those features of the signal sequence which are essential for initiating protein export is to generate mutations which alter the signal sequence of a secreted protein, resulting in the failure of the cell to export the protein from the cytoplasm.

The Gram-negative bacterium *Escherichia coli* provides a convenient system for isolating mutants which affect secretion, as genetic manipulations of it are relatively easy and many of its proteins are localised in the cell envelope, and, therefore, must be secreted through the cytoplasmic membrane. Evidence exists that signal sequences are involved in the export of proteins to at least two of the bacterial envelope compartments[5]. These compartments are the outer membrane and an aqueous layer located between the two membranes, called the periplasmic space.

One of the proteins found in the periplasmic space of *E. coli* is the maltose binding protein (MBP), a key component of the maltose transport system[6]. We recently described a selection procedure which enabled us to isolate mutants of *E. coli* which fail to secrete the MBP into the periplasm[7]. In the mutants we obtained, the MBP accumulates in the cytoplasm in its higher molecular weight precursor form. From the genetic data, we suggested that the mutations in these strains resulted in single amino acid substitutions in the MBP signal sequence. We now report the DNA sequence coding for the first 50 amino acids of

the wild-type MBP precursor, the identification of the signal sequence which was done through partial amino acid sequence determination, and the DNA sequence changes for several MBP export-defective mutants.

Partial determination of the MBP signal sequence using a *malE–lacZ* hybrid protein

Because the MBP precursor does not accumulate to appreciable amounts in wild-type cells, material for determining the MBP signal sequence was obtained from another source. We had previously isolated *E. coli* strains in which the *malE* gene encoding the MBP is genetically fused to the *lacZ* gene encoding the enzyme β-galactosidase[8]. The resultant hybrid gene codes for a hybrid protein which has at its amino-terminus an amino-terminal portion of the *malE* gene product and, at its carboxy-terminus, enzymatically active β-galactosidase. One such strain, PB4-81, synthesises a hybrid protein which is cytoplasmic and which seems, from the genetic and biochemical data, to include only a very small, amino-terminal portion of the *malE* gene product. Consequently, we suspected that this protein contained only a portion of the MBP signal sequence. Thus, this protein should provide material for a partial signal sequence determination.

The determination of the PB4-81 hybrid protein sequence was made possible by techniques developed for the sequence analysis of a hybrid protein between β-galactosidase and the *lac* repressor[9]. A partial signal sequence for alkaline phosphatase had been determined previously in this way[10]. The procedure used to generate hybrid proteins must result in the removal of at least the first 17 amino acids of wild-type β-galactosidase, thus eliminating the first methionine residue. If the amino acid sequence which replaces the normal β-galactosidase amino-terminus does not contain any methionine (other than the initiating methionine), only one new cyanogen bromide fragment (CNBr2*) should result from treatment of the hybrid protein. This proved to be the case with the hybrid β-galactosidase from strain PB4-81. Sequence analysis of the CNBr2* indicated that the first 14 residues are not derived from β-galactosidase (Table 1). These residues are derived from the

All sequencing was done using 0.1 M Quadrol in a Beckman 890C sequencer. The peptides were sequenced using a dual wash program . The intact carboxymethylated protein was sequenced with a program similar to that of Hunkapiller and Hood . All other procedures were as described previously , except that recently identification was also carried out with HPLC. + Indicates that the amino acid indicated was detected. A blank indicates either an ambiguous result or that it was not possible to detect the amino acid by this technique.

* Amino acids identified with an asterisk correspond to residues 19–34 of native *E. coli* β-galactosidase.

†The hybrid β-galactosidase was purified by the same procedure as for the *lac* repressor–β-galactosidase hybrid . Strain PB4-81 was grown in a 150-l New Brunswick fermentor at 30°C in medium 63 containing 1% glycerol and 0·2% maltose. The hybrid protein was purified 40-fold with a yield of 36% based on β-galactosidase activity. It was greater than 90% pure on SDS gels[22] and migrated with a mobility close to that of wild-type β-galactosidase.

‡ The hybrid protein was carboxymethylated and digested with cyanogen bromide as described elsewhere[21]. The CNBr2* peptide was purified using CM-cellulose and SP-Sephadex ion-exchange chromatography in 8 M urea and gel filtration on Sephadex G-50 in 30% acetic acid[21]. The radioimmunoassay used to monitor purification on CNBr2* has been described previously[9]. The yield of CNBr2* from purified hybrid protein was 25%. The elution volume on Sephadex G-50 suggested a size of about 90 residues. Amino acid composition data indicated that the PB4-81 CNBr2* contains lysine whereas wild-type CNBr2 has no lysine.

§ To confirm the presence of serine at residue 14 of CNBr2*, the peptide was cleaved with trypsin and the resulting peptides purified. Amino acid analysis of CNBr2* (corresponding to residues 9–23 of the intact protein) indicated two residues of serine and three residues of leucine. Details of the protein and peptide purifications and sequence analysis will be presented elsewhere (A.V.F., I.Z., P.J.B. Jr and J.B. in preparation).

amino-terminus of the protein to which β-galactosidase has been fused, in this case, the *malE* gene product. Two factors suggested that these 14 residues, along with the amino-terminal methionine from the hybrid protein, corresponded to the first 15 amino acids of the MBP precursor. First, this 15-residue sequence, with three basic residues among the first eight followed by several predominantly hydrophobic amino acids, is similar to other signal sequences. Second, none of this sequence was encountered when the protein sequence of the amino-terminal 25 amino acids of the mature MBP was determined (data not shown, see Fig. 1 legend).

DNA sequence of the wild-type *malE* signal sequence region

Cleavage of plasmid pHC5, which carries the *malB* operon (see Fig. 2), with the restriction endonuclease *Eco*RI, generates a fragment of 1,227 base pairs, comprised of 850 base pairs from the *malB* region of the *E. coli* chromosome and 377 base pairs derived from the vector (plasmid pBR322) (Fig. 2). This *Eco*RI–*Eco*RI hybrid fragment includes the promoter-proximal portion of the *malE* gene which codes for the MBP signal sequence region. Beginning with this fragment, a region of 600 nucleotides extending from the *Eco*RI cleavage site in the *malK* (ref. 11) gene in the direction of the *malE* gene has been sequenced on both strands, using the dideoxy/nick-translation technique of Maat and Smith[12]. This region includes the entire regulatory interval between the two *malB* operons and will be described elsewhere (H.B., in preparation).

We have taken the *Eco*RI cleavage site in *malK* on the strand encoding the MBP as the origin for numbering purposes. Starting from this point and examining the sequence towards the *malE* gene, the first ATG initiation triplet which is not soon followed in phase by a nonsense triplet is at nucleotides 457–459. Just before this point, at nucleotides 443–447, there is a 5-nucleotide sequence complementary to the 3'-OH end of the 16S rRNA (Shine and Dalgarno sequence[13]). This sequence suggests the existence of a translation start which is used *in vivo*. In fact, nucleotides 457–498 correspond to the first 14 amino acids of the MBP precursor, as determined from the protein sequence of the PB4-81 *malE–lacZ* hybrid protein described

above. Nucleotides 535–600 correspond to the first 22 amino acids of the mature MBP. Consequently, we deduce that the complete MBP signal sequence, that part of the MBP precursor which is excised to yield the mature protein, must be 26 amino acids long and encoded by nucleotides 457–534 (summarised in Fig. 1 legend).

Note that the serine at residue 15 of the PB4-81 hybrid protein (Table 1) is not derived from either the *malE* or the *lacZ* gene; neither can it arise from a simple fusion of the *malE* and *lacZ* genes within a codon. This serine residue may have been generated during the *in vivo* gene fusion technique which used bacteriophage Mu to obtain the *malE–lacZ* hybrid gene[8].

Sequencing the DNA of the *malB* region of MBP export-defective mutants

From the DNA sequence of the regulatory interval between the two *malB* operons, we identified a cleavage site for endonuclease *Hinf*I at nucleotide 406, and a cleavage site for *Ava*II at nucleotide 445. Restriction analysis revealed that the enzymes *Hinf*I and *Ava*II cleaved the *Eco*RI–*Eco*RI hybrid fragment of plasmid pHC5 at only one site each, this being the one identified from the sequence (Fig. 2). Simultaneous digestion of the hybrid fragment with *Hinf*I and *Ava*II yields two large fragments, as well as one small 39-base pair fragment corresponding to nucleotides 407–445 on the numbered strand.

To determine the sequence of the putative *malE* signal sequence mutations we had previously isolated, we used the technique developed by Sanger and co-workers[14] with the 39-base pair *Hinf*I–*Ava*II fragment serving as a primer. The advantages of this technique were as follows. (1) The genetic data on these mutations indicated that they were located early in the *malE* gene[7]. (2) These mutations were isolated directly on a transducing phage carrying the region of interest. Thus, phage DNA for each of the mutants could be used as template for the sequencing procedure after strand separation. (3) The *Ava*II end of the *Hinf*I–*Ava*II fragment is located 11 nucleotides from the beginning of the *malE* gene. This allowed us to read approximately 150 nucleotides into the *malE* gene in a single experiment.

Using this procedure, we have verified the wild-type DNA

Fig. 1 The DNA sequence of the first 144 nucleotides of the *malE* gene, corresponding to the first 48 amino acids of the MBP precursor. Only one strand, that with the same polarity as the *malE* message, is shown. Those amino acids underlined represent residues which were also determined from protein sequencing. The sequence beginning at residue 26 was determined on the mature MBP protein (A.V.F. and I.Z., unpublished). On the basis of protein sequencing, the evidence for glutamic acid at residue 3 of the mature MBP is tentative only. The arrow after residue 26 indicates the position at which the precursor is cleaved to yield the mature MBP. The five codon changes corresponding to the different signal sequence mutations are indicated above the position in the sequence where they occur, along with the predicted changes for the amino acid sequence.

sequence for the first 144 nucleotides of the *malE* gene which had previously been obtained by the dideoxy/nick-translation technique (Figs 1, 3).

Phenotype of MBP export-defective mutants

The mutations thought to result in MBP signal sequence alterations were initially obtained in a *malE–lacZ* hybrid gene carried on the λ transducing phage, λp72–47 (ref. 7). In this case, the hybrid gene encodes a hybrid protein that includes a substantial portion of the MBP, including the entire MBP signal sequence[8]. The mutations, which were located in the *malE* portion of the hybrid gene, were subsequently recombined into a wild-type *malE* gene on the bacterial chromosome. The resulting recombinants are Mal⁻ when scored on maltose tetrazolium agar, indicating that their ability to utilise maltose as a carbon source has been impaired. When they are induced for the expression of the *malEFG* operon, they accumulate the MBP precursor in the cytoplasm. However, these strains are not absolutely defective, for they grow slowly on maltose minimum medium and export a small amount of native MBP to the periplasm (see ref. 7). Furthermore, the mutants vary in their ability to utilise maltose, indicating that they may each affect the secretion of MBP to different extents (Table 2).

DNA sequence alterations in MBP export-defective mutants

Using the same sequencing procedure described above, we determined the DNA sequence of the promoter-proximal 144 nucleotides of the *malE* gene for nine spontaneous, independently isolated MBP export-defective mutants. The DNA used as template was obtained from the λ transducing phage on which the mutations were initially isolated (derivatives of λp72–47).

Each of the nine mutants sequenced exhibited an alteration in the region of the *malE* gene corresponding to the MBP signal sequence. Five different alterations were recognised (Fig. 7). The transition CTC (Leu) to CCC (Pro), resulting in a change in residue 10 of the MBP precursor, occurred in one mutant. The transversions GCA (Ala) to GAA (Glu) at position 14, ACG (Thr) to AAG (Lys) at position 16, and ATG (Met) to AAG (Arg) at positions 18 and 19 were encountered 3, 1, 2 and 2 times, respectively.

Discussion

We have presented here the DNA sequence of the MBP signal sequence and of mutant signal sequences which result in defective export of the maltose binding protein. The MBP signal sequence is similar to signal sequences which have been determined for other exported proteins in both prokaryotic and eukaryotic systems. Of the 26 amino acids comprising the MBP signal sequence, almost two-thirds are hydrophobic residues. Furthermore, all three charged residues present (two lysines and an arginine) are clustered in the first eight residues. Following

the arginine at residue 8, only the neutral amino acids serine and threonine interrupt the hydrophobic nature of the MBP signal. The amino acid just before the cleavage site in the MBP precursor is alanine. This is consistent with other signal sequences, where the residue here usually has a side chain with no more than one carbon moiety[4].

Fig. 2 The *malB* region of *E. coli* includes the *malE* gene and four other genes whose products are also components of the maltose transport system[23]. These are organised into two operons orientated in opposite directions and which diverge from the promotor region designated here as *Pmal* (ref. 24). The 1,227-base pair *Eco*RI–*Eco* RI hybrid fragment shown above is obtained by *Eco*RI digestion of plasmid pHC6. This plasmid carries a bacterial fragment of 1,750 base pairs which extends between cleavage sites in the *malB* region for restriction endonucleases *Sal*I (in *malK*) and *Bgl*II (in *malE*)[25]. This fragment was inserted between cleavage sites for *Sal*I and *Bam*HI in pBR322[26]. Details on the construction and characterisation of plasmid pHC6 will be presented elsewhere (J. M. Clement, D. Perrin and J. Hedgpeth, in preparation). Sites for cleavage of the hybrid fragment by *Ava*II and *Hinf*I are also indicated (see text).

The isolation of mutants with well defined alterations in the signal sequence of a secreted protein and in an outer membrane protein (see accompanying paper[15]) which result in the failure of the cell to secrete these proteins, provides the first genetic proof for the role of the signal sequence in the initial steps of protein secretion. Other workers on bacterial systems have suggested that the basic residues early in the signal sequence are responsible for the initial interaction of the precursor with the negatively charged inner surface of the cytoplasmic membrane[16,17]. Subsequently, according to this model, the hydrophobic portion of the signal begins to penetrate the membrane as the first step in the translocation process. Four of the five mutations we have characterised introduce a single charged residue into the hydrophobic core of the MBP signal sequence. Three of these mutations were found at least twice in independently isolated mutants. This strongly supports the notion that the hydrophobicity of the signal sequence has a key role in initiating protein export through the membrane. In the remaining case,

Fig. 3 Composite figure comparing autoradiograms of sequencing gels for the wild-type *malE* gene and the *malE* signal sequence mutations. Only the relevant parts of the gels are shown. *a*, The wild-type sequence. Points along the sequence where mutations were encountered are indicated on the left. The enlarged letter indicates the exact nucleotide that is altered in the mutants. *b–f* Represent the five classes of signal sequence mutations which we obtained in this analysis. The mutations shown in *e* and *f* correspond to those present in *E. coli* strains PB1101 and PB1102, respectively, as described in ref. 7.
the substitution of proline for leucine at residue 10 represents an exchange of hydrophobic residues. Proline does have the property of interrupting α-helices in polypeptide chains[18], so it is conceivable that secondary structure of the signal sequence plays a part in the initial steps of secretion.

The changes observed have differing effects on MBP secretion (Table 2). The two mutations with the strongest effects are 18-1 and 19-1, which change a hydrophobic to a charged amino acid. The three remaining mutations, which do not cause such a dramatic reduction in growth on maltose, involve a hydrophobic to hydrophobic amino acid change (10-1) and an uncharged to a charged amino acid change (14-1 and 16-1). These results are also consistent with the notion that the overall hydrophobic nature of this region is the most important feature for the secretion process.

All of the mutations we have obtained in the MBP signal sequence are point mutations which readily revert[7]. We hope to obtain additional information on the important structural features of the MBP signal sequence through a sequence analysis of such revertants.

Table 2 Growth properties of *malE* signal sequence mutants

Mutant no.	Growth on maltose minimal medium
Wild-type	+ + + +
10-1	+ +
14-1	+ +
16-1	+ + +
18-1	±
19-1	+

The mutants examined here are given numbers according to the amino acid position in the protein. Mutants 18-1 and 19-1 correspond to mutants 1101 and 1102, respectively, as described in ref. 7. The growth phenotype was determined by observing colony size on maltose minimal agar at 37 °C after 1 day. The hierarchy of growth rates corresponded exactly to the gradient of colours seen on maltose tetrazolium agar. For example, the wild-type parent forms white colonies, whereas mutant 18-1 formed the darkest red colonies on this agar. Mutant 16-1 forms a pink colony on the same agar, but apparently secretes enough MBP to the periplasm to allow near normal growth on maltose minimal media.

Sequence analysis of mutations that prevent export of λ receptor, an *Escherichia coli* outer membrane protein

Scott D. Emr[*‡], Joe Hedgpeth[†§], Jean-Marie Clément[†§], Thomas J. Silhavy[*‡] & Maurice Hofnung[†§‖]

The amino-terminal signal sequence is required for initiation of transmembrane protein transfer of the Escherichia coli λ *receptor protein. Mutations leading to insertion of charged amino acids into or deletion of amino acids from the hydrophobic segment of this sequence prevent export of this outer membrane protein.*

TRANSMEMBRANE protein transfer has been proposed to require information contained in a discrete portion of the protein molecule, called the signal sequence[1]. The export of proteins to the cell envelope of the Gram-negative bacterium *Escherichia coli* seems to proceed, in most cases, by the use of signal sequences[2]. Several examples have been found of proteins localised to either the outer membrane or the periplasmic space of this bacterium which are initially made as longer polypeptide chains containing signal sequences at their amino-termini. The preceding paper described the characterisation of mutants which prevent the secretion to the *E. coli* periplasm of the maltose binding protein[3]. In this paper, we focus on the transfer and localisation of an outer membrane protein, the bacteriophage λ receptor. This protein acts as the receptor on the cell surface for bacteriophage (ref. 4) and is also involved in the transport of maltose and maltodextrins[5,6].

The λ receptor protein is preferentially synthesised on membrane-bound polysomes[7]. In addition, it is initially synthesised in a larger precursor form[7,8]. Recent studies involving DNA sequencing of the early part of the *lamB* gene (which codes for the λ receptor protein) and amino acid analysis of the λ receptor precursor synthesised *in vitro* have revealed that this protein has a 25-amino acid signal sequence at its amino-terminal end[9].

We have devised a technique which has allowed us to select for mutations that prevent export of the λ receptor protein to the outer membrane[10–12]. In such mutant strains, the unprocessed precursor form of this protein accumulates in the cytoplasm. We describe here the sequence analysis of the DNA of 15 of these mutants cloned into a bacteriophage λ vector. These mutants and those described in the preceding paper[3] provide information concerning the role of the signal sequence in protein export.

DNA sequence of *lamB* gene in λ receptor export-defective mutants

The coding region for the amino-terminal 25-amino acid receptor signal sequence has been shown to be present on a 750-base pair *Sal*I DNA restriction fragment[9] (Fig. 1). The signal sequence is encoded by an early segment of this fragment. We have shown that 27 genetically and physically well characterised *lamB* mutations, which prevent export of the λ receptor pro-

tein, also map in this region[12].

We used the DNA sequencing method of Sanger *et al.*[13]. The well defined location of the mutations enabled us to select DNA primers that allowed sequencing of these mutations on both strands of the template DNA to ensure accuracy of the results. As shown in Fig. 1, the two primers chosen include a 67-base pair *Hpa*II–*Hin*fI fragment and a 51-base pair *Hpa*II–*Hpa*II fragment. The 115-base pair region between these two primers contains the entire coding region for the λ receptor signal sequence[9]. Separated DNA strands of the λ*apmalB*13*h*80 phage containing these mutations were used as templates[12,14] (see Fig. 1).

As previously described[12], the 27 *lamB* mutations affecting λ receptor export have been characterised as 14 point mutations and 13 deletion mutations. Detailed mapping of these independently isolated mutations has revealed that several of them are apparently repeats of the same mutational event. For this reason, only 15 of the 27 mutations were chosen for DNA sequencing. Eight point mutations and seven deletion mutations were sequenced.

The results (Fig. 2) of the sequences are: (1) all 15 mutations lead to alterations in the λ receptor signal sequence; (2) the eight point mutations represent single base changes in four distinct base pairs of the DNA. Three lead to a change in amino acid residue 15 (Ala to Glu), three in residue 19 (Met to Arg), one in residue 14 (Val to Asp) and one in residue 16 (Ala to Glu); (3) all the point mutations are transversions in the second position of each of four codons; (4) three of the deletions are internal to the portion of the DNA encoding the signal sequence. The remaining four deletions delete into this region of the DNA but are not confined to it.

Analysis of sequenced prokaryotic signal sequences

The DNA sequence of 15 mutations in the portion of the *lamB* gene encoding the λ receptor signal sequence has been determined. These mutations prevent export of the λ receptor protein to the outer membrane of *E. coli*, and instead, cause the accumulation of the precursor form of the λ receptor protein in the cytoplasm. These mutations and those described in the previous paper[3] represent the first genetic proof of the functional role of the signal sequence in protein export or secretion. The nature of the amino acid alterations caused by these mutations indicates components of the signal sequence that are critical for the initiation of transmembrane protein transfer.

A comparison between known prokaryotic as well as eukaryotic signal sequences indicates that they share several similar characteristics[15]. The seven known sequenced prokary-

Fig. 1 The λap*malB*13*h*80 phage contains the maltose transport genes, *malK,E,F,G* and approximately two-thirds of the *lamB* gene[14]. The putative λ receptor signal sequence mutations were recombined from the *lamB-lacZ* hybrid gene in which they were isolated into the portion of the *lamB* gene contained on this phage. The two critical *Sal*I sites used in the physical mapping of these mutations are shown[12]. To make template DNA for sequencing, phage DNA strands were separated on caesium chloride density gradients after heat denaturation in the presence of poly (U, G)[9,25]. The two primers used in the sequencing were derived from plasmid pHC5 (ref. 9). This plasmid carries a fragment of bacterial DNA which contains the entire *lamB* gene[9]. Plasmid DNA restriction fragments were separated on 4% polyacrylamide gels and were then electroeluted from the gel[26]. The two primers, *Hpa*II-*Hin*fI and *Hpa*II-*Hpa*II, were used to prime on the separated *l* and *r* phage DNA strands, respectively.
otic signal sequences (Fig. 3) can all be broken down into two principal segments, a short amino-terminal hydrophilic basic segment followed by a predominantly hydrophobic segment of amino acids that extends up to the site of processing. There are from one to three basic amino acids (Arg and/or Lys) in the basic portion of the signal sequence. These positively charged residues have been suggested to play a part in initial attachment of the polysomes to the negatively charged inner surface of the cytoplasmic membrane[15,16]. The hydrophobic segment directly follows the last basic residue in this initial segment. Charged amino acids, basic or acidic, are completely absent from this portion of the signal sequence. It has been suggested that this hydrophobic region loops into the membrane lipid bilayer or becomes associated with specific membrane protein(s), thereby initiating the transmembrane transfer of the polypeptide[1,15–17].

Possible mechanisms for the initiation of transport

The mutations described here for the λ receptor signal sequence and those described for the maltose binding protein (MBP)

signal sequence in the previous paper[3] argue strongly for a critical role of the hydrophobic segment of the signal sequence in the initiation of the export process. The four different single amino acid changes in the λ receptor signal sequence and four of the five amino acid changes in the MBP signal sequence are all changes from hydrophobic (Leu, Met, Val, Ala) or weakly hydrophilic (Thr) amino acids to very hydrophilic charged amino acids (Arg, Lys, Glu, Asp), and all these changes occurred in the hydrophobic segment of the signal sequence. These mutations, therefore, strongly support the requirement of the hydrophobicity of this segment.

Note that a similar alteration in the lipoprotein (another outer membrane protein) signal sequence at amino acid position 14 also affects this hydrophobic segment[33]. This mutation, which changes a glycine residue to an aspartic acid, does not have a dramatic effect on lipoprotein export, but does prevent processing of the lipoprotein precursor. The reason for this is not clear.

It is interesting that, in both the λ receptor and MBP systems, multiple copies of the same mutational events were isolated. In the λ receptor, at least, 17 of the 18 amino acid residues in the
Fig. 2 Sequences shown were determined using the chain termination procedure[13]. Sequence reactions were run on thin 8% polyacrylamide gels[27]. Gels were autoradiographed (Kodak No-screen X-ray film) for 12–24 h at −20 °C before reading off the above sequences. The signal sequence of wild-type λ receptor (top) and that of 15 *lamB* signal sequence mutations are shown. These mutations correspond to those present in the following *E. coli* strains: (1) SE2071; (2) SE2070, SE2079 and SE2105; (3) SE2099; (4) SE2069, SE2088 and SE2100; (5) SE2078; (6) SE2060 and SE2084; (7) SE2087; (8) SE2068; (9) SE2089; (10) SE2106. These strains are all described in detail in ref. 12. The amino acids to the right of deletions 7–10 above have not been confirmed by wild-type DNA sequencing. For this reason they are shown in italics. In (8), (9) and (10) above, the deletion end points are within codons. The amino acid directly following each of these deletions is, therefore, the result of a fused codon which may encode an amino acid not normally found at this position in the wild-type sequence.

Fig. 3 The amino acid sequence of seven known prokaryotic signal sequences. These include λ receptor[9], MBP[3], lipoprotein[28], β-lactamase[29], fd major phage coat protein[30], fd minor phage coat protein[31] and alkaline phosphatase[32]. Mutational alterations in the λ receptor signal sequence, the MBP signal sequence[3] and the lipoprotein signal sequence[33] are indicated below their corresponding wild-type sequences. The site of processing for these signal sequences is indicated above each sequence by an arrow.

hydrophobic portion of the signal sequence can be changed to charged amino acids by single base changes in the DNA. Despite this fact, of 14 independently isolated point mutations only 4 separate amino acids were changed. This suggests that only changes in a defined subset of the signal sequence amino acids will drastically affect export. (Although the *lamB* signal sequence mutants result in a λ-resistant phenotype, they are not totally defective in λ-receptor export, as small amounts are found in the outer membrane.) It may be that the lipoprotein mutation mentioned above has not affected such a critical amino acid. A more extensive mutant search will be necessary to confirm such a contention.

Export-defective mutations were not found in the amino-terminal basic segment of the signal sequence in either λ receptor or MBP. This might indicate that this portion of the signal sequence is not critical for protein export. Alternatively, the stringency of the selection for these mutations may not have allowed for detection of such mutants. The deletion and point mutations do, however, clearly demonstrate that this hydrophilic segment of the signal sequence is not sufficient for protein export.

The secondary structure of signal sequences has also been suggested to be important for the initiation of the secretion process[16]. Using available techniques for predicting polypeptide secondary structure[18,19], the structure of the λ receptor signal sequence and that of the mutants was determined. The results indicate that these mutations do not significantly alter the secondary structure of this signal sequence. Furthermore, the secondary structures of two signal sequences (for λ receptor and lipoprotein) seem to be quite different (unpublished results). However, the accuracy of these predictive techniques is questionable when considering such short peptides.

The fact that all the export-defective mutations studied lead to alterations in the signal sequence and not elsewhere in the proteins suggests that for these bacterial proteins the signal sequence is the only component of the protein required in the initial stages of translocation. Thus, the attachment of ribosomes to the cytoplasmic membrane and the initiation of the passage of such proteins through the membrane depend on an intact signal sequence. This agrees with synchronous translation experiments with the vesicular stomatitis virus glycoprotein which have shown that polysome binding to the membrane occurs at a time during translation when the signal sequence and little else of the polypeptide has been extruded from the ribosome[20]. However, it seems likely that other components of the exported proteins

are essential in subsequent steps of the secretion process which ensure that such proteins arrive at their proper final destination. That this is the case is supported by recent studies on the export of certain hybrid proteins[21,22].

The results of the DNA sequencing have also indicated how at least some of the *lamB* deletions may have occurred. The 36-base pair deletions present in SE2060 and SE2084 represent two of six deletions that are genetically and physically identical[12]. It is very likely that they are all the result of the same deletion event. Analysis of the DNA sequence in the region of the end points of this deletion reveals a segment of homology in direct repeat on either side of the deletion. There is evidence that limited homology of this type can promote specific deletion formation[23].

In genetic crosses of the λ receptor signal sequence mutants against *lamB*::Mu insertions, we found a very high percentage (18%) of the Mu insertions mapped under the 12-base pair deletion present in mutant SE2078[12]. DNA sequencing of this deletion reveals no obvious reason for the apparent preference of Mu for this site. However, several of the sequences known to flank Mu insertions are present within the 12 deleted base pairs, including the most commonly occurring sequence, CAG[24]. One can also detect DNA homologies in this region that would allow certain secondary structures in the DNA to form. The exact role these might have in Mu insertion is not clear. Continued analysis of new and other classes of apparent λ receptor signal sequence mutations should yield further insight into the mechanism of the important process of protein localisation.

The λ phage *att* site: functional limits and interaction with Int protein

Pei-Ling Hsu, Wilma Ross & Arthur Landy*

Section of Microbiology and Molecular Biology, Division of Biology and Medicine, Brown University, Providence, Rhode Island 02912

Site-specific integrative recombination of bacteriophage λ *involves unequal partners. The minimal phage* att *site is composed of approximately 240-base pairs and four distinct binding sites for Int protein, at least three of which are crucial for function. This 'donor site' recombines efficiently with a smaller 'recipient site' that lacks the extensive interactions with* Int *protein.*

THE integration/excision pathway of bacteriophage λ is a particularly favourable system for studying site-specific recombination at the molecular level (for reviews see refs 1, 2). Integration of the phage genome into the chromosome of the host occurs by a reciprocal recombination between the phage *att* site (POP') and the bacterial *att* site (BOB'). The products are two prophage *att* sites which comprise the left (BOP') and right (POB') junctures between bacterial DNA and the integrated prophage (the formal equivalent of this recombination is shown in Fig. 1*b*). Both the integration and excision reactions require the phage-encoded protein Int as well as the products of several host *Escherichia coli* genes[3]. An additional requirement for the excision reaction is the phage-encoded protein Xis. The Int and Xis proteins are 356 and 72 amino acids respectively, as determined from their encoding DNA sequences[4]. Recent *in vivo* experiments suggest that in some situations, Xis can partially replace, or be replaced by, the host factors[5]. Highly purified Int protein forms specific stable complexes with *att* DNA, has an enzymatic activity for cutting and resealing DNA strands, and is functional in an *in vitro* intermolecular recombination system[6–11].

A structural feature of integrative recombination, both *in vivo* and *in vitro*, is that the phage *att* site must be on a negatively supercoiled DNA molecule[8,11,12]. The cross-over event of Int-dependent recombination must take place within, or at the boundaries of, a 15-base pair core sequence that is common to all four *att* sites and is designated 'O' in the *att* site nomenclature[13]. DNA sequences of the four arms of the *att* sites, designated P, P', B and B', are all different from each other. The four *att* sites can also be distinguished from each other genetically by their distinctive behaviour in pairwise crosses[14–16].

The results reported here define the functional limits of the phage *att* site. We have also extended our studies of the interaction between Int protein and *att* sites[9]. The minimal phage *att* site is quite large (approximately 240 base pairs) and has several

widely spaced Int binding sites that differ in size and in response to heparin challenge. In contrast, the minimal sequence required for a phage *att* site partner (such as the bacterial *att* site) may not be much larger than the 15-base pair common core. We suggest a model in which integrative recombination involves two unequal partners; accordingly the phage *att* site is denoted the 'donor' and the bacterial *att* site or its analogue the 'recipient'.

Generating resected *att* sites

The λ phage *att* site is in the centre of a 492-base pair *Hind*III–*Bam*HI restriction fragment that extends from positions −251 to +242. (For numbering DNA sequences in this region of the λ chromosome, the centre of the common core region is taken as 0; positive numbers extend to the right, through the *int* and *xis* genes, and negative numbers extend to the left[13].) This *att*-containing restriction fragment was cloned into pBR322 in place of the *Hind*III–*Bam*HI fragment from the *tet* gene. The resulting plasmid, pWR1, carries all of the information necessary to specify a functional phage *att* site as determined by its competence for Int-dependent recombination with a bacterial *att* site *in vitro* (see below). This plasmid was used as the starting point for defining the functional limits of the phage *att* site. The question is then, how much DNA can be removed from around the phage *att* site without impairing its function?

When comparing different plasmids for relative amounts of phage *att* site function it is desirable that only one of the two phage *att* site arms should be altered at a time, and that non-*att* sequences (that is, plasmid DNA) adjacent to the different shortened termini should all be the same. We therefore generated phage *att* sites with incremental lengths of one arm as summarised in Fig. 1. The first procedure involved exonucleolytic digestion of the terminal nucleotides and cloning of the shortened *att* sites. An additional procedure involved reassortment of shortened arms between two *att* sites by Int-dependent recombination and recovery of the products.

Protocols were designed so that the final *att*-containing restriction fragments always have one *Hind*III and one *Bam*HI

terminus, thus facilitating subsequent cloning, restriction analysis and sequencing. The details for the construction of each plasmid will be described elsewhere.

Function of resected phage *att* sites

Competence for phage *att* site function was tested in an *in vitro* Int-dependent recombination system[10,11]. In the assay conditions used the phage *att* site must be on a supercoiled molecule[11] and the bacterial *att* site functions best when it is on a linear molecule (K. Mizuuchi, personal communication). Control experiments established that this assay registers only phage *att* site function on the supercoiled parent, and not prophage *att* site function (Fig. 3, right panel).

All plasmids carrying a P arm equal to or longer than that of pPH54 (−160) recombined efficiently with the bacterial *att* site, but none of those carrying a shorter arm (−115 or less) did so (Fig. 2 and Table 1). Thus some DNA between positions −160 and −115 is essential for the proper functioning of the P arm in a phage *att* site.

A family of P' arm-shortened plasmids generated as outlined in Fig. 1*a*, had a constant left terminus at -115. Because this did not include all the information required for a functional P arm (see above and Fig. 2), a longer P arm was restored to each plasmid as outlined in Fig. 1*b*. All *att* sites with P' arms equal to or greater than that of pPH307 (+82) were efficient recom-

bination partners, whereas those with shorter P' arms (+64 or less) failed to recombine efficiently (Table 1). The shortest P' arm that functions as a phage *att* site contains essentially all the DNA identified as forming heparin-resistant complexes with purified Int protein[9]. The longest P' arm which fails to function as a phage *att* site contains only half of this sequence.

To test whether the combination of a minimal P arm and a minimal P' arm is sufficient for full function, a phage *att* site carrying both minimal arms was constructed. A *Hind*III–*Hinf*I fragment from −160 to −115 (from pPH54) and a *Hinf*I–*Bam*HI fragment from −115 to +82 (from pPH307) were cloned together into the *Hind*III–*Bam*HI sites of pBR322. The resultant plasmid, pPH507 (−160 to +82), thus contains all the elements of a minimal P arm and a minimal P' arm, as defined by the experiments described above.

The function of this plasmid was compared with that of pPH7 (−115 to +82), pPH10 (−115 to +46) and pPH510 (−160 to +46). In recombination with the bacterial *att* site pPH507 recombined as well (60–100%) as the control plasmid pWR1, whereas the other three gave no detectable recombination (Fig. 3). In these assay conditions, supercoiled plasmid DNAs carrying the bacterial *att* site or the left or right prophage *att* sites all failed to recombine efficiently with the linear bacterial *att* site (Fig. 3). Therefore, the competence of pPH507 must reflect phage *att* site function (and not prophage or bacterial *att* site
Fig. 1 Construction of plasmids carrying resected *att* sites. *a*, Plasmid pWR1 was first linearised, for example with *Hind*III for shortening the P arm. Digestion of the linear DNA with a combination of exonuclease III from *E. coli* (New England Biolabs) and nuclease S₁ (Miles) generates a series of shortened plasmids carrying flush base-paired termini. A chemically synthesised decamer *Hind*III linker (Collaborative Research) was ligated to the blunt end by T4 DNA ligase. Digestion with *Hind*III and *Bam*HI generates a family of fragments with unaltered P' arms and P arms shortened to different extents. These were fractionated by gel electrophoresis and regions corresponding to the desired size were excised and eluted. Finally, the size selected fragments were recloned between the *Hind*III and *Bam*HI sites of pBR322 and the plasmid carried in each clone characterised by restriction fragment analysis. In an analogous fashion, shortening of the P' arm would be carried out by using *Bam*HI in the place of *Hind*III to linearise the plasmid and using a *Bam*HI linker in place of the *Hind*III linker. *b*, Cells harbouring a plasmid with a shortened *att* site arm were infected with λ phage carrying a wild-type *att* site. As a result, some of the infecting phage underwent Int-dependent recombination with the *att* site on the plasmid and thus acquired the ability to transduce amp^R (D. Kamp and K. Mizuuchi, personal communication). The *att* site at each phage–plasmid junction has one arm derived from the plasmid and the other arm derived from the phage. Recovery of the recombinant *att* site on a self-replicating plasmid was accomplished by digesting the plasmid–phage hybrid DNA with *Hind*III, recircularising the DNA (by means of the *Hind*III ends) and selecting ampicillin-resistant transformants. These procedures will be described in detail elsewhere (P.-L. H. and A.L., in preparation). /

Fig. 2 Integrative recombination of plasmids with resected P arms. Each reaction mixture contained ~1 µg supercoiled plasmid DNA with an intact, or P arm-resected, phage *att* site and 1µg of linear DNA with a bacterial *att* site (*Eco*RI–*Bam*HI fragment; 1,600-base pairs) at a molar ratio of 1:3. The recombination was carried out in a 20-µl mixture containing 50 mM Tris-HCl (*p*H 7.4), 5 mM EDTA, 40 mM KCl, 12.5 mM spermidine, 4 µl of sonicated bacterial extract and 1.5 µl of Int fraction I (refs 8, 10) After incubation at 25 °C for 40 min, 30µl of a buffer containing 0.3 M NaCl, 10 mM Tris-HCl (*p*H 7.4) was added and the samples were extracted with phenol-CHCl₃ before being loaded onto a 1% agarose slab gel and electrophoresed at 35 V for 16 h in E buffer (40 mM Tris, 20 mM Na-acetate, 2 mM EDTA, 18 mM NaCl, adjusted to *p*H 7.9 with acetic acid). The gel was strained with EtBr(1 µg ml⁻¹) for 15 min and then photographed under UV light. For quantitation the fragment containing the bacterial *att* site was first end-labelled with ³²P by T4 polynucleotide kinase[9]. After recombination and gel electrophoresis, portions of the gels corresponding to the unreacted linear DNA and the recombination product were excised and counted individually for ³²P radioactivities. The percentage of phage *att* site molecules that recombined with labelled bacterial *att* site DNA (present in threefold molar excess) was calculated as follows:

$$\% \text{ phage } att \text{ sites recombined} = \frac{^{32}\text{P radioactivity in the product band}}{\text{total } ^{32}\text{P radioactivity}} \times 3$$

The P arm end point of each resected plasmid, as determined by restriction enzyme analysis or by DNA sequencing is shown at the bottom (also see Table 1). All plasmids contain a P′ arm extending to the *Bam*HI site at position +242. Positions on the electropherogram are indicated for the ³²P-labelled linear DNA containing the bacterial *att* site (*att*B), the unlabelled circular plasmid DNA containing the intact or resected phage *att* sites and migrating as supercoils (s.c.) or nicked circles (n.c.), and the linear ³²P-labelled products of recombination (arrows). Binding sites for Int protein (■) (see legends to Figs 4 and 5), and the 15-base pair common core sequence (hatched) are indicated on the linear map of the *att* site region.
function). We conclude that the sequences delimited by the minimal P and P′ arms (−160 to +82) are both necessary and sufficient for phage *att* site function.

Sequence and Int binding of minimal phage *att* site

Most of the DNA comprising the minimal region required for phage *att* site function was included in our reported sequence extending from −114 to +203 (ref. 13), within which two specific sites of Int interaction were detected[9] (see below). One of these 30–35-base pair binding sites has at its centre the 15-base pair common core sequence where the cross-over occurs in recombination. The second site is in the P′ arm (+50 to +86) and the sequence protected by Int extends to the right boundary of (3 to 4 bases beyond) the minimal length P′ arm. Clones lacking part or all of this P′ arm Int binding site failed to function as phage *att* sites (Fig. 3 and Table 1), indicating a requirement for this Int interaction for phage *att* site function (see below).

We now report the sequence for the remaining DNA in the P arm that is required for phage *att* site function as well as sequence extending further to the left (Fig. 4). The sequence from −250 to −200 is 47% A+T, in contrast to a relatively uniform distribution of 62% A+T from −200 to −115. When combined with the previously determined sequence[13] this yields an average base composition of 71% A+T for the minimal phage *att* site.

The newly sequenced P arm region was examined for additional Int binding sites using the technique of DNase footprinting[17]. In the presence or absence of Int protein a singly end-labelled restriction fragment was digested with a nonspecific

nuclease in conditions where each molecule was cut approximately once. On a DNA sequencing gel the end-labelled fragments form a ladder, with gaps at those positions protected by Int. Using a restriction fragment that extends in both directions beyond the minimal phage *att* site, we observed that Int protects four regions from digestion by the AT-specific antitumour agent neocarzinostatin (Fig. 5*a*). Two of these regions correspond to

Table 1 Integrative recombination of plasmids with resected P arms or resected P′ arms

Plasmid	End point		% Relative recombination†	
	P arm	P′ arm	Expt 1	Expt 2

* The end points of these plasmids were determined by restriction fragment analysis. All other end points were determined by DNA sequencing.
† See Fig. 2 for quantitation. The results are normalised to 100% for pWR1. The absolute value for pWR1 in each experiment is shown in parentheses.
Fig. 3 Integrative recombination of the minimal phage *att* site. The *in vitro* recombination reaction and gel electrophoresis were carried out as described in Fig. 2 legend. The structure and boundaries of the cloned fragments used in the left panel were confirmed by restriction fragment analysis and by DNA sequencing. The extent of each cloned fragment is indicated by a long bar beneath the map of the *att* site region. The *att* sites carried by plasmids in the right panel are: pWR1-phage *att* site (*Hind*III-*Bam*HI-492), pWR101-bacterial *att* site (*Eco*RI-*Bam*HI-1,600), pPH201-left prophage *att* site (*Eco*RI-*Bam*HI-1,300) and pPH202-right prophage *att* site (*Hind*III-*Bam*HI-800). Positions on the electropherogram are indicated for the 'recipient' linear DNA containing the bacterial *att* site (*att*B), the 'donor' circular plasmid DNA containing truncated or intact phage *att* site and migrating as supercoils (s.c.) or nicked circles (n.c.) and the linear products of recombination (arrows). Binding sites for Int protein (■) (see legends to Figs 4 and 5), and the 15-base pair common core sequence (hatched) are indicated on the linear map of the *att* site region.

the common core and P′ arm binding sites[9]. The two others are located in the P arm, within the minimal phage *att* site; P arm site 1 extends from −148 to −129, and P arm site 2 from −116 to −98 (see also Fig. 4). Good agreement with these results was obtained by monitoring DNase I digestion of the complementary (bottom) strand (Figs 4 and 5*b*). These two binding sites are most probably the basis for nitrocellulose filter retention of Int complexed with P arm-containing restriction fragments[18].

The importance of P arm site 1 is indicated by the fact that its removal abolished phage *att* site function (Figs 2, 3). However, it cannot be determined from exonuclease resection experiments whether P arm site 2 is also necessary. Base changes or deletions within P arm site 2 will be required to clarify this point.

An additional feature of Int–DNA interaction was visualised by DNase I, but not neocarzinostatin digestion. With Int concentrations higher than the minimum required to observe specific protection there was a series of strongly enhanced bands at 10-base pair intervals (Fig. 5*b*, lane 1, positions −75, −85,

−95, −117 and −128). Similar patterns of enhanced DNase I cutting were also observed to varying extents on other restriction fragments in regions surrounding the common core and P′ arm binding sites (data not shown), but not to the left of P arm site 1 (Fig. 5*b*). These results are to be distinguished from the possibly related observation that exonuclease digestion produced a 10-base pair pattern within the Int-protected sequence of the P′ arm[18].

Structural relations between Int binding sites

The P arm Int binding sites (15–20 base pairs) are each shorter than either the common core or the P′ arm sites, but are comparable in size to the 15-base pair protected region in the *att*B common core[9] (Fig. 6). However, the P arm sequences do not share homology with the common core sequence or with the core–arm juncture sequences[9].

The common core and P′ arm Int binding sites show very little sequence homology with each other, possibly suggesting their

Fig. 4 Sequence of the left portion of the P arm and location of Int binding sites P arm 1 and P arm 2. P arm sequence is given negative numbers proceeding leftward from the centre of the common core region (0). We have previously reported the sequence from −114 to +203 (ref. 13). DNA sequence was determined for both strands (with the exception of −252 to −237) by the method of Maxam and Gilbert[27] using 5′ termini labelled with ³²P by polynucleotide kinase[9]: top strand sequence from −241 to −90 was obtained from the *Hind*III end of the *Hind*III (−251)–*Alu*(−6) fragment (see ref. 13); top strand sequence from −252 to −241 was determined using the *Eco*RI site of pBR322 in the plasmid carrying the *Hind*III(−251)–*Bam*HI(+242) *att* fragment (pWR1, see text). Complementary

sequence, from −116 to −237, was obtained from the *Hinf*I end of fragment *Hinf*I(−115)-*Mnl* I (recognition site at −231). The left boundaries of the shortest functional P arm (−160, pPH54) and the longest nonfunctional P arm (−115, pPH55) obtained in these experiments are indicated (⌐→). The locations of Int-binding sites P arm 1 and P arm 2 were determined by the method of DNase I footprinting[17] with modifications described previously[9] (see also Fig. 5). Int protection of sequences in the top strand from neocarzinostatin[28,29] digestion (■) was carried out using two different fragments, each labelled at the *Hind*III end: *Hind*III(−251)–*Alu*(−6), carrying only P arm sequences, and *Hind*III(−251)–*Hpa*II(+305), carrying the entire minimal phage *att* site sequence (shown in Fig. 5*a*). Int protection of the bottom strand from neocarzinostatin (■) or DNase I (□) digestion was carried out on a fragment from plasmid pPH310 containing *att* sequence from +46 to −251 (*Hind*III), labelled at the *Bam*HI linker adjacent to position +46. Partially protected bases are designated ▨▨▨ . Ambiguities in the precise boundaries of the protected regions are due to the failure of neocarzinostatin (●) or DNase I (○) to cut certain bases in the control digests. An inverted repeat structure (→ ←) which includes sequence from each of the two Int-binding sites plus additional sequence between the two sites is indicated.
interactions with different domains of the Int protein. In contrast, however, each of the P arm sites shares a considerable uninterrupted homology (11-base pairs in P arm 1 and 8-base pairs in P arm 2) with the left portion of the P' arm site. The two P arm sites also share this homologous sequence but with an inverted orientation, such that P arm 1 is a direct repeat and P arm 2 is an inverted repeat of the P' homology. A number of bases in the sequence shared among the P' and P arm protected regions have been identified as 'contact' sites in the Int–DNA interaction, as defined by methylation-protection experiments with the P' site (data not shown). Included within the left half of the P' site is the 7-base pair sequence, TCACTAT, which, in addition to being part of the homology with the two P arm sites, is found (with one mismatch) in the right half of the P' site.

Int binding in the P' arm has the unique property of resistance to challenge by the polyanion heparin (Fig. 5a and ref. 9). Furthermore, in studies with DNA carrying only the P' arm site (data not shown) we have established that the heparin-resistant binding is not dependent on the presence of the other binding sites. Thus, Int binding and resistance to heparin challenge are intrinsic features of the P' arm sequence. As Int binding at sequences homologous to the left half of the P' arm site (P arm sites 1 and 2) did not show the property of heparin resistance (Fig. 5a), the right half of this site, which is essential for recombination (Table 1), might be responsible for heparin resistance.

We have also used the footprinting assay to examine restriction fragments carrying other combinations of one to three Int binding sites (data not shown). The P arm 1 site was capable of binding Int when present singly. The common core region, when tested using a fragment containing *att* sequence from −115 to +46, bound Int independently of the P arm 1 and P' sites. Quantitative measurements to determine whether there are subtle differences in binding affinities as a function of the simultaneous presence of two or more binding sites have not yet been carried out.

Efficient partners for phage *att* site

From *in vivo* Int-dependent crosses it was found that the phage *att* site recombines most efficiently with the bacterial *att* site and less efficiently with itself or either of the prophage *att* sites[14–16]. Similarly, in the *in vitro* conditions used here the phage *att* site recombined most efficiently with the bacterial *att* site. (Both *in vivo* and *in vitro* relative recombination values are strongly affected by reaction conditions and it is therefore difficult to make quantitative comparisons between them[16,19–21]).

In our *in vitro* experiments the supercoiled phage *att* site recombined with the linear bacterial *att* site at a level of approximately 50% and with the linear right prophage *att* site (*att*R) at a level of approximately 5–10% (Fig. 7). With the linear left prophage *att* site (*att*L) the level of recombination was just above background in this experiment (not visible in the reproduced photograph), and recombination with the linear phage *att* site was not detectable. The relative recombination efficiencies were affected significantly by factors such as Int concentration, and this aspect of the reaction is being investigated. Nevertheless, we always found that a linear bacterial *att* site gave very high values and a linear phage *att* site gave very low values in their respective recombination patterns with supercoiled phage *att* site. Is this difference due to the presence of unique features that confer competence on the linear bacterial *att* site, or is it due to certain features on the linear phage *att* site (and linear *att*L) that inhibit recombination with a supercoiled phage *att* site?

Four plasmids containing the common core and different combinations of P or P' arm Int binding sites (as described in Fig. 3) were used as linear partners for a supercoiled phage *att* site (Fig. 7). It is clear from the fact that linear pPH10 recombines

Fig. 5 Footprints of Int binding on restriction fragments containing: *a*, the entire minimal phage *att* site (using neocarzinostatin); or *b*, the P arm and common core regions (using DNase I). *a*, In lanes 1–3 the restriction fragment *Hin*dIII(−251)–*Hpa*II(+305), ^{32}P-labelled at the 5′ end of the top strand (*Hin*dIII), was partially digested with neocarzinostatin[28,29] in the absence (lane 3) or presence of purified Int protein at 10 μg ml⁻¹ (lane 2) or 20 μg ml⁻¹ (lane 1). The Int–DNA complex in lane 1 was challenged with heparin before neocarzinostatin digestion. Sequence markers for this restriction fragment, A+G (lane 4), and C+T (lane 5), were prepared according to the method of Maxam and Gilbert[27]. Details of these methods and electrophoresis conditions have been described previously[9]. A linear map of the minimal phage *att* site region depicts the relative sizes and positions of the four Int protected sequences (■) seen in the neocarzinostatin footprint. Also indicated are the boundaries (−160 and +82) of the smallest functional *att*P region obtained in these experiments (see Fig. 3) and the 15-base pair common core sequence (hatched). *b*, In lanes 1–3 a restriction fragment from plasmid pPH310, containing *att* sequence from +46 to −251(*Hin*dIII) (labelled at the 5′ end of the bottom strand at the *Bam*HI linker adjacent to position +46), was partially digested with DNase I in the absence (lane 3) or presence of purified Int protein at 2.5 μg ml⁻¹ (lane 2) or 5 μg ml⁻¹ (lane 1). The footprinting and electrophoresis conditions were as described previously[9]. The common core region has been run off this gel. Positions of enhanced cutting by DNase I (→) at ~ 10-base pair intervals (−75, −85, −95, −117, −128) are indicated in lane 1.

Fig. 6 Comparison of Int-protected sequences in the bacterial and phage *att* sites. The sequence shown for each binding site is the maximum length of DNA protected by Int from either neocarzinostatin or DNase I digestion (see Figs 4 and 5 and ref. 9). The sequence of the P arm 2 site has been inverted (compare Fig. 4) to facilitate comparison of sequence homologies. A 6-base pair homology between the two common core sites and the P' arm site is indicated by a line between the two strands of sequence (——). Homologies between the left portion of the P' arm site and each of the two P arm sites are indicated (—)(see text). A 7-base pair sequence in the left half of the P' arm protected region, found within the sequence shared with the two P arm sites, is also found, with one mismatch, in the right half of the P' arm site (●).

efficiently with supercoiled *att*P that an efficient partner for the phage *att* site requires neither the P arm 1 nor the P' binding sites. In this test of integrative recombination the bacterial *att* site does not possess any unique features that cannot be provided or mimicked by a phage *att* site lacking the P arm 1 and P' Int binding sites (compare lanes 2 and 6, Fig. 7).

The only difference between the two *att* sites that recombined efficiently with *att*P and the two that failed to recombine significantly was the presence of the P' arm Int binding site. Thus, the presence of the P' arm site on the linear partner was unnecessary, and actually interfered with its ability to recombine with a supercoiled phage *att* site. The P arm 1 binding site did not contribute as much interference (Fig. 7, compare pPH10 and pPH510). The interfering effect did not seem to be due to titration by the P' arm binding site as it was not abolished by higher concentrations of Int.

Discussion

Our results reveal the involvement in recombination function of approximately 240-base pairs of DNA adjoining the cross-over locus. Similar experiments, using a different method for obtaining shortened *att* sites, have been carried out by Mizuuchi and Mizuuchi[22]. In addition, they found function for an *att* site in which bacterial DNA is substituted for phage DNA up to position −152 (8-base pairs less than our shortest functional P arm, pPH54 and pPH507). Therefore, it is probable that a clone carrying phage *att* site DNA from positions −152 to +82 (235-base pairs) would also be functional.

The diversity of the Int binding regions, both in sequence and in size (Fig. 6) is surprising. Considerable sequence homology is found among the three sites in the P and P' arms, but the sequence in the common core binding region does not share this homology. Sequence differences are almost certainly respon-

sible for the unique heparin-resistant character of binding in the P' arm site. The lack of homology between the core and the other sites could reflect more than one DNA-binding domain within the Int protein, or a single domain responding differently to the respective sequences. It is clear, however, that Int has at least two distinct capabilities. In addition to the 'structural' or DNA-binding properties involving sequences quite distant from the cross-over site of recombination, Int also has a nicking-closing (topoisomerase) activity[10]. Although no specificity for the phage *att* site has yet been demonstrated in the topoisomerase assays, it is clear from our results that Int does interact specifically with the normal substrate for this enzymatic activity[9].

The nature of the role of the distant Int binding sites in the P and P' arms is much less apparent. Int binding seems to be an intrinsic feature of the individual DNA sequences since protection was seen for the P arm 1 and P' sites when present singly and for the common core in the absence of the P arm 1 and P' sites. The kinetics has not yet been studied, however, and it is possible that there is facilitation of binding at one site by Int bound at another site.

The two size classes of Int binding sites, approximately 30–35-base pairs and 15-base pairs, could reflect differences in the number of bound Int monomers. Similarities between the two P arm sites and each half of the larger P' site also suggest the possibility of higher order Int complexes. The linear distance between the P arm 1 and P' Int binding sites, or between the common core and either of these sites, is not incompatible with a three-dimensional structure in which a loop of DNA would bring any of these sites together in the same Int complex. For example, the distance between non-contiguous sequences which are in close proximity in the three-dimensional structure of the nucleosome is estimated to be approximately 80-base pairs[23]. By analogy with studies on nucleosomes[24,25] and DNA gyrase

Fig. 7 The efficiency of different *att* sites as linear recombination partners. The *in vitro* recombination reactions and gel electrophoresis were performed as described in Fig. 2 legend. Each reaction mixture contained supercoiled pWR1 (1.5 μg) and linear recipient DNA in a three to one molar ratio. The linear plasmids were generated by *Pst*I digestion of pPH7, 10, 507, 510 or by *Eco*RI digestion of pWR1, pWR101, pPH201 and pPH202. The origin and boundaries of the restriction fragments carried by each plasmid are described in Fig. 3 legend. Positions are indicated on the electropherogram for DNA containing different 'recipient' *att* sites (linear plasmid), the 'donor' circular plasmid DNA (pWR1) containing the phage *att* site and migrating as supercoils (s.c.) or nicked circles (n.c.) and the linear product of recombination (arrows).
complexes[26] the 10-base pair pattern of enhanced cutting around the binding sites (Fig. 5b) is suggestive of DNA wrapping around, or lying on, the surface of a higher order oligomer of Int. This idea is consistent with the electron microscope observation of Int complexes (8–10 monomers) interacting with the phage *att* site (Bob Yuan, personal communication).

Although their specific functions have not yet been defined, it is clear that the P arm 1 and P′ Int binding sites have critical roles in recombination. Further experiments will be necessary to ascertain whether the P arm 2 binding site is also critical and whether the observed Int–DNA interactions are influenced by host factor proteins or by negatively supercoiled DNA substrate.

Our results suggest a model for integrative recombination that involves two unequal partners. The large size and complexity of the phage *att* site contrasts with the smaller size and simplicity of its partner. We refer to the phage *att* site, which must be supercoiled and which provides most of the structural information and specificity for the reaction, as the 'donor' molecule. A 'donor' *att* site recombines efficiently with an appropriate 'recipient' *att* site, such as the bacterial *att* site. Although we have yet to define the minimal requirements for 'recipient' *att* sites, several properties are known. We have shown previously that Int binding to the bacterial *att* site results in the protection

of a short (approximately 15-base pairs) DNA sequence at the left core–arm juncture[9]. The present results (and additional data, not shown) establish that a 'recipient' *att* site does not require the presence of the P arm 1 or P′ arm binding sites. Furthermore, the absence of the P′ site is necessary for a good 'recipient' *att* site. The sequence homology between the shortened phage *att* site (pPH10) and the bacterial *att* site, together with their respective Int protection patterns, suggests that an efficient 'recipient' site may not be much larger than the common core and partially homologous core–arm junctures[13]. Additional experiments will be necessary to confirm, and possibly extend, the applicability of this 'donor–recipient' model for integrative recombination.

* Palomar Observatory, California Institute of Technology, Pasadena, California 91125
† Institute for Astronomy, University of Hawaii, Honolulu, Hawaii 96822

The properties of the remarkable double quasar 0957 + 561 were first described by Walsh et al.[1]. Recently Young et al.[2] have described CCD observations of a distant galaxy associated with the quasar pair, and have identified this galaxy as a gravitational lens forming a double image of a single quasar. We report here 1.2–2.2-μm observations of the system that support the conclusion that the twin quasars are a pair of images of a single object; the quasar has an energy distribution that is unusual. The intervening galaxy is shown to be highly luminous with a bolometric luminosity of about $2 \times 10^{11} L$.

As described by Walsh et al.[1] the system consists of two 17th magnitude visual objects with redshift $z = 1.4$; they refer to these as A and B, object A lying 5.7 arc s north of B. The galaxy
Fig. 1 The flux density plotted versus observing diaphragm for 1.6 and 2.2 μm. ●, Observations centred on 0957 + 561A; ○, observations centred on 0957 + 561B. × indicates an observation made with a 12.5 arc s diaphragm centred between the two quasars. The solid lines are fits of a point source plus galaxy contribution in diaphragms centred on the quasars. The change in flux with diaphragm diameter for the galaxy is scaled from the visual observations of Young, et al.[2].

* At 5-m Hale telescope.

found by Young et al.[2] lies 0.8 arc s north of B; it has a redshift of 0.4 and has angular dimensions of the order of 5 arc s.

The observations reported here consist of IR photometry of the twin quasars at 1.6 and 2.2 μm through a series of diaphragms. These observations were obtained using the 3-m telescope of the NASA IR Telescope Facility at the Mauna Kea Observatory and the 5-m Hale telescope on Palomar Mountain. The most extensive observations were obtained on the nights of December 16 and 17 1979 at Mount Kea in conditions when the seeking disk was ≤1 arc s. Variations in seeing during the multiple-diaphragm observations were accounted for by observing the star ϕ Ursae Majoris as a secondary standard before each observation of the quasar pair. This sequence was repeated for each wavelength and each diaphragm used. In addition to the multiple diaphragm observations on each quasar, observations were obtained at 1.2, 1.6 and 2.2 μm with a 12.5 arc s diaphragm centred between the two quasars.

Table 1 and Fig. 1 show the observed flux densities within various diaphragms centred on quasars A and B. The 1.6- and 2.2-μm observations of quasar B show a strong dependence of flux on observing diaphragm, the observed 2.2-μm flux doubling between the 3 and 8 arc s diaphragms. This observation clearly shows the presence of extended IR emission in the vicinity of quasar B. A similar, but much smaller, effect is also seen in the observations of quasar A.
Fig. 2 The energy distributions of the quasars 0957 + 561A (●) and B (○) from 0.35 to 2.2 μm. The data have been corrected for the contribution of the underlying galaxy and represent only the quasar contributions. At visual wavelengths, the flux densities for quasar B are taken as 0.72 of quasar A, as per Young et al.[2].

We interpret the extended emission as being due to the galaxy identified by Young et al.[2]. To separate the contributions to the multiple-diaphragm observations from the galaxy and from the quasars the light distribution for the galaxy, as reported by Young et al.[2], has been numerically integrated for various diaphragms centred on quasars A and B. The IR observations centred on quasar B were first fitted as the sum of a quasar component which is constant with diaphragm plus a galaxy component for which the IR flux density was assumed to follow the visual light distribution as measured by Young et al.[2]. The best fit to the observations centred on B is included in Fig. 1 and listed in Table 2; for this fit, 42% of the 2.2-μm flux density in a 3-arc s diameter diaphragm arises in the intervening galaxy. To determine the flux densities of quasar A, the galaxy contribution to the observations centred on A was determined from the fit to the observations centred on B. The best fit to these observations is also shown in Fig. 1.

The ratio of fluxes of the B and A quasars are $F_\nu(B)/F_\nu(A) = 0.80 \pm 0.15$ and 0.74 ± 0.15 at 1.65 μm and 2.2 μm respectively. These ratios are consistent with the ratio of B/A found visually by Young et al.[2] of 0.75 ± 0.04 and at radio wavelengths of 0.80 ± 0.05 (refs 3, 4). Thus, in all observed wavelength ranges, the two quasars have a constant flux ratio, consistent with the achromatic imaging predicted by the gravitational lens model. This conclusion is valid if there is no significant difference in the extinction along the two separate light paths through the intervening galaxy.

The 0.35–2.2-μm continuum distribution of the quasars shown in Fig. 2 is unusual. The increase in flux density from $10^{14.5}$ to 10^{15} Hz in the quasar rest frame is rare; of the 39 quasars observed by G.N. et al.[5] all but one show a negative spectral index at these wavelengths. The similar energy distribution of quasars A and B make them far more similar to each other than to any other known quasar. This again strongly suggests the idea that these objects are two images of a single physical object, rather than two quasars in the same cluster.

Because the light emitted from the galaxy dominates the flux longward of 1 μm, the properties of the galaxy can be inferred from a fit to the IR observations. Figure 3 shows the energy distribution of the galaxy in a 7-arc s diaphragm; Table 2 gives the flux densities of the whole galaxy at 1.2, 1.6 and 2.2 μm. Young et al.[2] find an R magnitude for the entire galaxy of $R \sim 18.5 \pm 0.2$ mag; thus $(R-[2.2])_{galaxy} = 4.3 \pm 0.3$ mag and $([1.6]-[2.2])_{galaxy} = 0.8 \pm 0.3$ mag. These colours are consistent with those found for luminous galaxies at a redshift of around 0.4 by S. E. Persson, K.M. and G.N. (unpublished results).

Table 2 Derived flux densities

	1.2 μm*	1.65 μm	2.2 μm
0957 + 561 A	0.6 ± 0.1	0.60 ± 0.06	0.47 ± 0.07
0957 + 561 B	0.4 ± 0.1	0.48 ± 0.06	0.35 ± 0.06
Galaxy (12.5 arc s)	0.6 ± 0.3	0.95 ± 0.15	1.23 ± 0.15

* The flux densities derived at 1.2 μm are based on extrapolations and have unknown systematic uncertainties.
Fig. 3 The energy distribution from 0.35 to 2.2 μm of the galaxy associated with the quasars 0957+561A, B as derived from observations in a 7 arc s diaphragm centred on the B quasar. At all wavelengths, the contribution from the quasars have been subtracted from the observed flux to yield this energy distribution. At 1.2 μm the equivalent flux density in a 7 arc s diaphragm has been derived from observations in a 5 arc s diaphragm. The visual observations are from Young *et al.*[2].

If the Hubble constant $H_0 = 60$ km s^{-1} Mpc^{-1} and the deceleration parameter $q_0 = 1$, the luminosity of the galaxy in the observed wavelength range 0.4–2.2 μm is $2 \times 10^{11} L_\odot$, establishing it as a highly luminous galaxy. If the energy distribution of this galaxy resembles that of the giant elliptical galaxy M87, which has a bolometric luminosity of $1.3 \times 10^{11} L_\odot$ (ref. 6), then the bolometric luminosity of the lens galaxy in the double quasar system is $2.4 \times 10^{11} L_\odot$.

In conclusion, IR observations of the double quasar 0957+561 A,B support the gravitational lens model of these objects in two significant ways.

(1) The ratio of the IR flux densities of the two components is the same as found in the visual and at radio wavelengths. Furthermore, the derived energy distributions for the two components are the same and extremely unusual. This strongly supports the suggestion that quasars A and B are indeed two images of the same physical object.

(2) The IR properties of the lens galaxy are entirely consistent with it being a giant elliptical galaxy at a redshift of ~0.40.

We thank J. Gunn, J. Oke, S. Persson, A. Stockton, D. Walsh, G. Rieke, and P. Young for discussions and for letting us see their data before publication. We also thank our telescope operators J. Carrasco, R. Koehler and B. Shaeffer. This work was supported by NASA grants NGL 05-002-207 and NASW-3159 and NSF grants AST 77-20516 and AST 78-26028. Spectra of interplanetary scintillation

T. W. Cole & O. B. Slee

Division of Radiophysics, CSIRO, Sydney, Australia

A new type of radio spectrograph is described here which has been used to observe the interplanetary scintillation of a radio source over a two-to-one frequency range. Simultaneous observations over this range provide a direct insight into the time variations of intensity and the physical form of the interplanetary irregularities producing them. A specific example shows the direct way in which the spectral record can indicate the physical details of the electron density variations of the interplanetary medium.

The scintillation of small-diameter radio sources[1] due to scattering in the outer layers of the solar corona has been analysed statistically[2,3] and the observations fit the theory of diffraction at a thin screen reasonably well[4]. The corona is subject to strong day-to-day variations, and some of the inconsistencies would be due to the non-simultaneous observations at the specific frequencies used in these comparisons. However, the theories are not complete and particular problem areas include[3,5] the actual form of the irregularities, and an excess of enhanced emission occurring as the scattering moves from being weak to strong—the r.m.s. phase deviation on the wavefront emerging from the screen increases to 1 rad and beyond. It is in these areas that the spectral observations are particularly illuminating.

The observations are made with a new and unique form of radio spectrum analyser, the acousto–optical radio spectrograph. The broadband radio signal from the radio telescope is converted to a travelling ultrasonic wave in a solid medium. A Bragg interaction between the travelling ultrasonic beam and a transverse, collimated beam from a helium–neon laser produces diffracted light whose angular intensity distribution can be shown to be the power spectrum of the applied radio signal [8,9]. In the observations discussed here, the Parkes 64-m radio telescope was used with a broadband feed and amplifier in such a way that the frequency range 280–520 MHz was analysed by the spectrograph. The optical output was detected by a self-scanned array of photodiodes and digitized [6,7]. The 240 MHz bandwidth was resolved into 256 simultaneous channels and complete spectra were recorded on magnetic tape 25 times per second.

Source 3C273 was observed on 10 and 11 October 1978, when its line of sight was 13° (0.23 AU) from the Sun's centre. At this position the current theory[4] predicts that the mean r.m.s. phase deviation, ϕ_0, varies from ~0.65 to ~0.35 rad over 280–520 MHz respectively and that the scale size, a_0, of irregularities, assumed to have a correlation distribution $\exp(-r^2/2a_0^2)$, is ~55 km. If one defines a Fresnel distance z_0 as $2\pi a^2/\lambda$, these values of a_0 correspond to z_0 varying between 0.12 and 0.25 AU over 280–520 MHz respectively. On an average day one would be well into the 'far-field' of the diffraction. A sample of the data obtained on 11 October is shown in Fig. 1 with a 40-ms time resolution and smoothed to 53 frequency channels over the range 280–520 MHz. Without resorting to statistical analysis one can see that the variations are highly correlated over the frequency range and are dominated by both weak and strong curved ridges of emission which take about 1 s to sweep across the frequency range.
Fig. 1   An example of the intensity variations of source 3C273 due to interplanetary scintillation. Systematic structure on the frequency–time plane is evident. The figure is plotted with a frequency resolution of 4 MHz, time resolution of 40 ms, and white represents increased intensity.

As suggested by Hewish, the simplest explanation for the curved bands in Fig. 1 is that a normal, random diffraction pattern has been refracted by large wedge-shaped irregularities which are themselves too large to produce intensity variations. This would account for the increasing curvature at lower frequencies, where the refractive index of the plasma is also higher.

However, the dynamic spectrum reveals details which cast doubt on such an explanation. It can be seen that Fig. 1 contains bands of a characteristic shape. That is, the curvature at any frequency is always of essentially the same magnitude although the sign of the curvature can vary. The refracting wedges would need to be of constant wedge angle. The wedge would also need to change sharply from this angle to the negative value of the same angle within 1 s to explain sections of Fig. 1 such as at 10 s and 41 s. An even greater difficulty is illustrated by Fig. 2, where the section of Fig. 1 at around 45 s is shown in greater contrast. As at other parts of the record, bands of opposite sign are observed superimposed. Multiple refracting wedges in the line of sight would simply add the refracting angles algebraically and one could not expect to maintain the characteristic curvatures observed.

Further details are revealed in the more intense bands, one of which is displayed in higher contrast in Fig. 3. The peak intensity takes about 1 s to sweep across the frequency range. At an assumed solar wind speed of 400 km s^{-1}, this represents an angular displacement of 400 km in 1 AU or 0.55″. If the refractive index (and hence refracting angle) of the plasma varies as f^{-2}, then it is 3.5 times greater at 280 than at 520 MHz. The 0.55″ then represents the difference in refraction angles or 2.5 times the refraction angle at 520 MHz. The increasing curvature to the band indicates a typical refraction angle of 0.22″ at 520 MHz and 0.77″ at 280 MHz.

Figure 3 also indicates a feature visible on all the stronger bands of Fig. 1. At the higher-frequency end and always on the

inside of the curvature is a region of intensity which is reduced below the mean intensity level. This is also indicative of refraction if the figure is interpreted as interference between a plane wave and a wave impinging at an angle. The strong band is a region of constructive interference and the reduced intensity is where a half-wavelength phase difference produces destructive interference. These successive interference fringes are seen to be about 0.6 s apart in time at 520 MHz or 240 km for an assumed solar wind speed of 400 km s^{-1}. The corresponding angle at 520 MHz is a half-wavelength in 240 km or 0.25″. Both the curvature and fringes indicate the origin for the band as
Fig. 3   A high-contrast picture of a strong band reveals the characteristic increasing curvature and the successive bright and dark interference fringes at the higher frequencies.

being due to refraction. The interference fringes are, however, also incompatible with the refraction being due to a large wedge. With a large wedge the background wave would also be refracted and the interference would not be observed.

An alternative explanation is that the bands are the result of individual refracting elements in the interplanetary medium. That is, at least for this solar elongation, there are insufficient irregularities in the line of sight to produce a random diffraction pattern. A picture emerges of irregularities in the form of comparatively sharp gradients in the plasma density. This picture is quite different from that usually assumed and certainly different from the 'weakly scattering' assumptions at the basis of work such as that of Uscinski[3]. The observed fact that strong, individual bands or 'spikes' are seen only at the smaller solar elongations[5] is also consistent with one seeing fewer irregularities in the line of sight and, at least for the stronger cases, the effects of individual irregularities.

Fig. 2   A section of Fig. 1 is reproduced with increased contrast to illustrate the superposition of bands of opposite curvature.

More observations, analysis and modelling are to be done, but even these preliminary results suggest the value of dynamic spectral observations in the analysis of interplanetary scintillations. Just as spectral observations of scintillations from the ionosphere gave greater insight[8] than single-frequency studies, so the spectral observations reported here extend single-frequency interplanetary studies. The fact that single-frequency observations of interplanetary scintillations might obey Rayleigh statistics is not always sufficient proof that a random scattering medium is actually involved. One possibility suggested here is of systematic diffraction from sharp density gradients.

We thank Itek Corporation for the spectometer's modulator and Professor A. Hewish for help in our understanding of the scintillation process.

An alternative interpretation by A. Hewish*

Cole and Slee have suggested that their beautiful observations of interplanetary scintillation cannot be explained by conventional models of the solar plasma. I do not share their view and now outline my reasons for believing that the new data reinforce the standard theory.

On conventional models, derived from spacecraft and radioastronomical data, the solar plasma contains density irregularities having a three-dimensional wavenumber power spectrum $P(K)$ which approximates to a Kolmogorov spectrum $P(K) \propto K^{-11/3}$ for irregularities on a scale $10^6 \text{km} > 2\pi K^{-1} > 10^3\text{km}$. Evidence for a flattening of the spectrum for $2\pi K^{-1} < 10^3\text{km}$ has been reviewed elsewhere[1,2]. At a solar elongation of 13°, and at 400 MHz, Readhead *et al.*[1] predict intensity fluctuations on a time scale of about 0.7s, with a scintillation index of about 0.75, and which correlate over a band of about 200 MHz. These features are in good agreement with Fig. 1.

It is well known that irregularities on a scale larger than about 10^3km (at this elongation) give reduced intensity fluctuations at 400 MHz because the Earth is then within the near-field zone. The larger irregularities, therefore, introduce phase gradients across the incident wavefront. I have shown elsewhere[3], in connection with the interstellar scintillation of pulsars, that scintillation due to small-scale irregularities combined with phase gradients due to large-scale irregularities produces characteristic frequency drifts similar to those observed by Cole and Slee. The drift rate is

$$\frac{\text{d}\nu}{\text{d}t} = \pm \frac{V\nu}{2Z\theta_r}$$

where V is the drift velocity of the diffraction pattern, Z the distance to the irregularities, and θ_r the angular refraction corresponding to the phase-gradient. This phenomenon was originally discussed by Shishov[4].

The observations of Cole and Slee show frequency drifts which change sign in about 5 s, corresponding to a periodicity of roughly 10 s. This requires irregularities of scale $2\pi K^{-1} \sim 4 \times 10^3\text{km}$ assuming a solar wind speed of 400 km s^{-1}. The model of Readhead *et al.*[1] indicates a phase modulation $\phi \sim 0.53$ rad at 400 MHz for small-scale irregularities which produce scintillation on a time scale of about 0.7 s. Assuming $P(K) \propto K^{-11/3}$

we derive $\phi \sim 0.53(10/0.7)^{5/6} \simeq 5$ rad for the integrated phase modulation on scales up to 4×10^3 km. Putting $\theta_r \sim \phi K \lambda/2\pi \approx 0.2$ arc s we obtain $\text{d}\nu/\text{d}t \sim \pm 390 \text{ MHzs}^{-1}$ for $Z = 1$ AU and $\nu = 400$ MHz. This drift rate is typical of many features seen in Fig. 1. The question of simultaneous drifts with opposite sign mentioned by Cole and Slee raises no problems. The magnitude of θ_r ensures that wave fronts refracted convergently at a distance of 1 AU must, on arrival at the Earth, be overlapping for $\sim 10\%$ of the total time, leading to the superposition of patterns having drifts in opposite directions. The convergence and divergence of wave fronts suggest that overlap regions should be flanked by bands of negative slope on the preceding side, and positive slope on the following side, which is certainly true for the feature at 45 s discussed by Cole and Slee. They should also be associated with a higher mean intensity which can again be seen.

Finally it should be mentioned that the 'spiky' nature of the intensity variations is typical of diffraction patterns at distances not too far from the 'focusing' distance of the random irregularities. This property has been reviewed by Uscinski[5]. I conclude that the standard theory, involving the integrated effect of many 'weak' irregularities along the line of sight, is in excellent agreement with the present observations. I believe that more extended data of this kind could add considerably to our knowledge of $P(K)$.

Crystal structure of Ag · TCNQ

N. Uyeda, T. Kobayashi, K. Ishizuka & Y. Fujiyoshi

Institute for Chemical Research,
Kyoto University,
Uji, Kyoto 611, Japan

High resolution electron microscopy (HREM) has been used for the direct imaging of complex crystal structures. High resolution at an atomic level cannot be expected from most organic crystals due to their high sensitivity to electron radiation damage, although we [1] have previously considered the conspicuous images of chlorine and copper atoms in chlorinated copper phthalocyanine molecules as a special case dependent on the very radiation-resistant property of the compound. In practice, however, some organic crystals may be able to withstand the dosage necessary for the image recording itself but could not tolerate the extra dosage necessary for searching the proper image field and for successive careful focusing. In this respect, the principle of the minimum exposure proposed by Williams and Fisher[2] is attractive as it might reduce the unnecessary damage which takes place before the actual image recording. We describe here the structure images of a metal complex of 7 7', 8, 8'-tetra-cyanoquinodimethane (TCNQ) with the resolution of an atomic level obtained by developing an automated device which is basically similar to that by Unwin and Henderson[3]. The electron microscope equipped with the low dosage device was JEM-200CX, which gives the instrumental resolution of 0.24 nm.

The various metal salts of TCNQ behave as the charge transfer complexes which show interesting electronic and magnetic properties. A thin crystalline film of complex salt forms by solid state diffusion when a thin film is prepared in the form of a double layer by the successive vacuum condensation of TCNQ and metal on a suitable substrate[4]. If the metal film is deposited on TCNQ crystallites which have been epitaxially grown in advance on a KCl cleavage face, the reaction leads to a

Fig. 1   SAD pattern from a crystallite of Ag.TCNQ salt taken with the incident electron beam parallel to the c-axis of a tetragonal unit cell.

topotactic formation of the complex crystallites which eventually assume characteristic orientations. This type of solid state formation of complex salts was found to be possible in general with many metals such as Al, Ag, Au, Co, Cs, Cu, Fe, Li, Mn, Ni, Ti and Zn. In the present work, we used very thin crystallites of Ag · TCNQ because the medium heavy ions such as silver were expected to give sufficient contrast for the clear recognition of their individual images. The selected area diffraction (SAD) indicated that the crystal assumes a tetragonal unit cell the dimensions of which are $a = 1.25$ nm and $c = 0.70$ nm. With the electron beam incident normal to the specimen habit face, the single crystal pattern presents a characteristic tetragonal symmetry as shown in Fig. 1 and the reflections are expected to contribute to the formation of high resolution images. To avoid the confusing effect of the dynamical electron scattering on the image formation, the crystal thickness was carefully controlled to be as thin as 3nm by monitoring it with a quartz crystal microbalance.

The images of Ag · TCNQ complex salt were recorded on Fuji FG films for 0.7 s at the electron optical magnification of 170,000 with the electron dosage of ~0.2 C cm^{-2}. The optical density of the film developed with Kodak D-19 was <0.5, causing a considerable amount of photographic noise which was enhanced by the quantum fluctuations in the images. To increase the signal-to-noise ratio the final images were translationally averaged over the crystal periodicities along the two tetragonal axes by applying the photographic multiple exposure technique. An enlarged photomicrograph of the structure image thus obtained is reproduced in Fig. 2a.

The characteristic features of the structure image are the square net pattern composed of the obtuse zigzag lines and the rod-like figures of roughly 0.3 nm in width all located in the middle of the elemental squares. As each rod is orientated to be normal to those in the neighbouring squares, the two dimensional unit cell is assigned as the large square indicated in Fig. 2, showing a good agreement with that expected from the diffraction data. Note the high contrast dots at every knot of the net structure. Both ends of the individual rods are related to the square sides at their re–entrant tips.

The structure of this crystal had been analysed using the modified multislice calculation of the electron diffraction
Fig. 2   *a*, Enlarged electron photomicrograph of Ag · TCNQ crystallite showing the images of Ag ions and TCNQ anions as indicated by the inserted molecular diagram. *b*, Computer-simulated images of the structure based on the projection as indicated by the schematic diagram. The imaging conditions of JEM-200CX are: the defocus spread, 15 nm, the illuminating angle, 0.1 mrad; and the Δf for the Scherzer focus, 55 nm.

intensities, although the details are not presented here. The molecular arrangement obtained as the preliminary result is shown in Fig. 2b which presents the theoretical images computer-simulated with the atomic parameters and the actual imaging conditions taken into account. Comparison of these two images clearly shows that the contrast distribution in the real images can be interpreted in terms of the molecular and ionic arrangements as indicated by Fig. 2a. The re-entrant side of each square corresponds to the chain of N–C–C–C–N, and the oblong rod can be regarded as the benzole ring, although they are all the columnar projections of 7–10 identical species. On the basis of this remarkable coincidence, the dark dot which is visible at every knot of the net structure can be regarded as the image of Ag ions superimposed in the direction of the column axis.

As far as the projection along a proper axis is concerned, this type of molecular and metal ionic arrangements show remarkable similarities to those of K, Na and Rb salts of TCNQ determined by Richard et al.[5], Konno and Saito[6], and Hoekstra et al.[7], respectively. In particular, the K salt seems to show the closest resemblance as its projection along the a-axis of a monoclinic unit cell almost produces a tetragonal symmetry in the molecular and ionic arrangements. The TCNQ complexes of

other metals such as Al, Au, Cs, Cu, Li and Ni were found by SAD to assume structures which are all isomorphic to the present Ag salt when prepared by the solid state topotaxy. In fact, Hoekstra et al.[7] has found by X-ray diffraction that the Li salt has a tetragonal unit cell although no detailed structure analysis has been performed.

The critical radiation dose($\sim$0.3 C cm^{-2}) of the present complex is measured by applying 100-kV electrons to the fading time method. This dose is less than those for some aromatic compounds which are known to be rather radiation-resistant. However, the atomic resolution is attainable only if the minimum exposure technique is applied to those organic crystals which are radiation-resistant to this extent.

Inelastic electron tunnelling spectroscopic study of lubrication

A. Bayman & P. K. Hansma

Department of Physics, University of California, Santa Barbara, California 93106

Inelastic electron tunnelling spectroscopy reveals the vibrational spectrum of organic molecules on the oxide of a metal-oxide–metal junction[1-3]. A vibrational mode of frequency ν appears in the tunnelling spectrum as a peak in the second derivative of voltage with respect to current, d^2V/dI^2, at a voltage $V = h\nu/e$ (where h is the Planck's constant, and e is the electron charge). Both IR and Raman active modes can be observed. Tunnelling spectroscopy[4,5] has been used as an effective surface probe in the studies of adhesion[6-8], biochemistry[9,10], water pollution[11], damage due to electron beam irradiation[12], or UV irradiation[13], surface chemistry and catalysis[14-18]. We report here a new application of tunnelling spectroscopy—to lubrication—and present spectra of 1,2 hexadecanediol, hexadecanol and hexadecanoic acid and relate the results to their properties as boundary lubricants for aluminium. Because diols give the best results in both friction measurements and tunnelling spectra, we studied the adsorbtion of the smallest diol, ethylene glycol, and found that both OH groups react with the alumina surface.

As the experimental details are described elsewhere[2], we only give an outline here. We evaporated an aluminium strip 700-Å thick onto a clean 1×3 inch glass slide and oxidized the aluminium strip by venting the chamber to pure O_2. When a thicker alumina layer was needed to produce a junction of the desired resistance we thermally oxidized the strip in air at 200 °C. We doped the oxidized aluminum strip either with a liquid solution of the molecules of interest or a vapour. Before vapour doping the alumina was cleaned in an argon glow discharge[19]. We completed the junction with a 3,500 Å thick evaporated lead cross strip.

We checked the electrical resistance of each junction with a low-power ohmmeter. Doped junctions with resistances in the range 100–1,000 Ω were acceptable. For the spectra to be taken the slide was mounted on the sample holder with small screw clamps which made the electrical connections to the evaporated electrodes. The junction assembly was then immersed into liquid helium at 4.2 K and tested for the proper current–voltage tunnelling characteristics to ensure that all the current flow was
Fig. 1 Tunnelling spectra of C_{16} molecules with different attachment groups. The compounds are doped at the same concentration, 0.05%, from an emulsion of 90% D_2O and 10% hexane.

due to tunnelling. Second derivative spectra were then obtained by detecting the second harmonic voltage due to a small modulation current with a lock-in amplifier as a function of voltage.

Figure 1 shows the inelastic electron tunnelling spectrum of hexadecanol, hexadecanoic acid and 1,2-hexadecanediol. The compounds were doped from an emulsion of 90% D_2O and 10% hexane at a concentration of 0.05%. Among the three spectra 1,2-hexadecanediol has the most intense peaks. It also gave the most reproducible results. The second harmonic intensity, plotted on the y axis, is an intensive quantity independent of junction area and resistance[20]. The peak highs are a measure of surface coverage[21]. The acid was the most difficult to work with. It often gave shorted junctions indicating damage to the junction's oxide layer. The alcohol adsorbed least, as indicated by the relatively small peaks. From these observations, we guess that the diol would be the best lubricant: it had strong, reproducible adsorbtion without damaging the oxide.

Hotten's measurements of the load-carrying and wear-reducing properties of emulsions containing long-chain alcohols and diols show that the failure load is higher and aluminium
Fig. 2 Tunnelling spectra of ethylene glycol, deuterated ethylene glycol and a clean junction. The ethylene glycol and the deuterated ethylene glycol were doped at 1×10^{-3} torr and 3×10^{-3} torr for 1 min and 4 min respectively. The OH or OD vibrations of the diols are not present in the spectra implying that the hydroxyl groups lose their protons and attach to the oxidized aluminium surface through their oxygens.
Fig. 3 Tunnelling spectra of 1,3-butanediol. The same surface species results from vapour doping or liquid doping from different solutions. The vapour doping was at 1×10^{-3} torr for 100s. The liquid doping concentrations were 25%, 50%, 12% and 20% by volume for the H_2O, the D_2O, the emulsion of 80% D_2O and 8% hexane, and the benzene respectively.

wear is lower (by a factor of ~ 3) for 1,2 and 1,3 diols compared with the corresponding alcohols[22]. Although there have been experiments to determine the lubrication properties of long chain acids on aluminium[23], no direct comparison is possible with the diols.

The emulsion that was used was meant to model the emulsions typically used in the lubrication of aluminium during rolling and cutting operations. An important difference is that D_2O was substituted for H_2O. This D_2O should have exchanged the two protons on the hydroxyl groups of the diol, the one on the carboxylate group of the acid; and the one on the hydroxyl group of the alcohol. Note, however, that there are no OD bands in the spectra. (They would be expected between 2,400 and 2,700 cm^{-1}.) This indicates that all these exchangeable protons are lost during bonding of the compounds. This was anticipated in the case of the alcohol and the acid. Greenler[24], Evans and Weinberg[15], and Evans *et al.*[16] showed that alcohols absorb as alcoxides on alumina, losing the proton of their hydroxyl group. Klein *et al.*[25], Hall and Hansma[26], Brown *et al.*[27], Lewis *et al.*[28] and others showed that acids adsorb as carboxylate ions on alumina, losing the proton of their carboxylate group. Figures 1–3 show that diols lose protons from both hydroxyl groups.

Figure 2 shows the spectra of ethylene glycol, totally deuterated ethylene glycol and a clean junction. Ethylene glycol is the smallest molecule that has the same attachment group as 1,2-hexadecanediol. There are no peaks in the tunnelling spectra where the O–H and O–D vibrations for ethylene glycol should occur[29,30] which shows again that the molecule loses its protons from both hydroxyl groups during bonding to the aluminium oxide surface. Unfortunately there are no IR or Raman spectra available for metal salts of ethylene glycol with which we can make a direct comparison of our spectra. The most we can say is that there is a good comparison between our observed peak positions and those of model compounds such as p-dioxane[31] and glycol nitrate[32] which contain the X–O–CH_2–CH_2–O–X structure.

Does the vapour doping technique that is useful for these small molecules give the same surface species as would be deposited from a lubricant solution? Figure 3 shows the tunnelling spectra of 1,3-butanediol vapour doped and liquid doped from various solvents. Every peak in the vapour-doped spectrum is present in the other four spectra which shows that the surface species formed is independent of the doping technique and solvent used. The similarity of spectra doped from both aqueous solutions to the others also suggests that the water is not chemically modifying the oxide layer: not converting the oxide layer to a hydroxide. Note that deuteration of the OH groups by the use of D_2O as a solvent gives the same spectrum as with H_2O. This is consistent with the results for ethylene glycol and 1,2-hexadecanediol.

Inelastic electron tunnelling spectroscopy can reveal the surface adsorbed species from model lubricant solutions. Long chain 1,2- and 1,3-diols which are effective boundary lubricants chemisorb to the aluminium oxide surface more readily than the corresponding alcohols or acids and they are less destructive to the oxide layer than acids. In diols both hydroxyl groups react with the alumina surface. The same surface species is formed from both vapour doping and liquid doping from polar and non-polar solvents and emulsions.

Ferromagnetic coupling to muscle receptors as a basis for geomagnetic field sensitivity in animals

David Presti* & John D. Pettigrew

Beckman Laboratories of Behavioral Biology, California Institute of Technology, Pasadena, California 91125

Over the past decade several investigators have provided convincing evidence that the orientation of pigeons and other birds during homing and migrational activities is significantly affected by Earth-strength (<0.5 G) magnetic fields[1-8]. The presumed mediator of such effects would be a highly sensitive magnetoreceptor which the birds would normally use to extract navigational information from the geomagnetic field. The recently reported measurement of magnetic remanence in honeybees[9] and in homing pigeons[10] has stimulated interest in the possibility that the magnetically sensitive structure may be constructed from permanently magnetic material. Here we report the detection of permanently magnetic material in the neck musculature of pigeons (*Columba livia*) and migratory white-crowned sparrows (*Zonotrichia leucophrys*). We propose that a magnetic field detector might involve the coupling of magnetic particles to a sensitive muscle receptor such as a spindle. A detection mechanism of this kind could account for the difficulties encountered in conditioning immobile homing pigeons to magnetic field changes[11,12] and for the puzzling requirement of movement in other behavioural experiments involving pigeons and magnetic fields[13,14].

As behavioural experiments suggest that the magnetically sensitive structure in the homing pigeon might be located in the head or neck[1,2], we concentrated on this region. We tested for the presence of permanently magnetic material by measuring specimens in a SQUID (Superconducting Quantum Interference Device) magnetometer, an instrument used extensively by geologists to measure palaeomagnetic remanence in rocks[15] and also used in earlier studies of honeybees[9] and pigeons[10]. Birds were freshly perfused with phosphate-buffered formaldehyde (4%, pH 7.4), as the acid pH of unbuffered fixative might attack magnetic iron oxides. All dissections were conducted with clean glass microtome knives to prevent possible contamination from metallic instruments. To maximize the signal from any permanently magnetic material present, specimens were exposed to a 1,000-G field from a small cobalt-samarium magnet immediately before being measured in the magnetometer. This exposure has the effect of increasing the alignment of any permanently magnetic moments; the resulting measurement is termed inducible magnetic remanence.

Eleven homing pigeons from our Caltech loft (eight of local stock; three of an Oregon stock specifically chosen for their ability to orientate in overcast conditions; aged from 12 days to 12 years) and eight local feral pigeons were tested using the SQUID magnetometer. Inducible remanence of magnitude 1.0×10^{-6} to 1.5×10^{-5} e.m.u. was found in the head and neck area of all 19 pigeons tested (Table 1). Within the head, reproducible remanence was found to be associated with the skull. This remanence was diffuse, being spread rather uniformly throughout the entire skull; we could find no visible magnetic structures in the skull. This is in contrast to the results of Walcott *et al.*[10] who found permanently magnetic material in the pigeon head to be concentrated in a small, unilateral, innervated piece of tissue between the dura and the skull. We also found reproducible inducible magnetic remanence in the neck musculature of the pigeon, especially in the complexus muscle and associated fascia (Table 1).

* To whom correspondence should be addressed.

Seven migratory white-crowned sparrows (all adults at least one season old) were also tested for inducible magnetic remanence in the head and neck (Table 1).

In addition to pigeons and white-crowned sparrows, frozen specimens of approximately 40 other species of birds were tested for inducible magnetic remanence in the head and neck. Widely varying results from $<10^{-6}$ to $>10^{-5}$ e.m.u. were found; however, all cases of appreciable remanence were associated with migratory birds (for example, tree swallow [*Iridoprocne bicolor*], 5×10^{-6} e.m.u.; western grebe [*Aechmophorus occidentalis*], 9×10^{-6} e.m.u.; pintail duck [*Anas acuta*], 6×10^{-6} e.m.u.).

We were able to visualize magnetic material imbedded in the neck musculature of three homing pigeons (aged 3, 11 and 12 years) and two white-crowned sparrows. This material had the form of diffuse patches of black magnetic material in fascia or muscle (Fig. 1) or particles of black magnetic material embedded in muscle fibres. The black magnetic material was sometimes found together with transparent orange crystals possibly similar to those associated with magnetic material in chiton teeth [17,18] and also reported by Walcott *et al.* [10] in pigeons. Electron probe X-ray analysis (MAC-5-SA3 electron microprobe) of magnetic material from the neck musculature of pigeons and white-crowned sparrows indicated that iron was the major elemental component. This, together with the black colour and appreciable permanent magnetism, suggests that the material is probably composed largely of magnetite (Fe_3O_4), in agreement with the conclusions of previous reports of magnetic remanence in honeybees[9] and in pigeons[10]. Remanence of 1.0×10^{-6} e.m.u. could be produced by approximately 6×10^9 0.07-μm cubic single domain particles of magnetite[16] (amounting to 10^{-8}g), provided their magnetic moments were all aligned. If the magnetic domains interact, adjacent moments would tend to cancel and a larger amount of magnetite would be required to produce the same remanence.

Geomagnetic field sensitivity in animals may arise from the coupling of small permanent magnets to sensory structures which originally evolved to serve other functions. Animal skeletal muscle is richly innervated with sensory fibres which supply receptors sensitive to pressure and stretch. One such receptor type, the muscle spindle, is acutely sensitive to stretch and has a major role in the regulation and perception of muscle movement, both at the spinal and supraspinal levels[19-21]. We propose that permanently magnetic grains, coupled to such a muscle receptor so that the torque exerted on the grain ensemble in the geomagnetic field is sufficient to stimulate the muscle receptor, might form an effective basis for magnetic field sensitivity. This proposal is, of course, motivated by our finding of significant reproducible magnetic remanence and visualizable iron-rich magnetic material in the neck musculature, although we think it unlikely that the large visualizable deposits in the older birds are more than epiphenomenal.

One important implication of a muscle spindle-based magnetic field sensor is that natural motion of the muscle may be requisite for the perception of magnetic stimuli. This suggestion is based on the findings of several experiments with humans which indicate that perception of muscle spindle discharge is
Fig. 1 Highly magnetic black particles (induced remanence of approximately 15×10^{-6} e.m.u.) found between the surface of the complexus muscle and the superficial fascia of a 3-yr-old homing pigeon. The particles are imbedded in a sheet of fascia. Unstained whole mount. Scale bar, 25 μm.

indirect, and seems to be possible only with reference to movements initiated by the subject[22-24]. This might account for one slightly puzzling aspect of geomagnetic field sensitivity in homing pigeons; namely, the failure of several investigators to condition a cardiac response to magnetic stimuli in the laboratory[11,12]. In these experiments the pigeon is held immobile in the centre of coils with which the ambient magnetic field can be altered. Also intriguing are the results of laboratory experiments by Bookman[13,14]. He found that homing pigeons could be trained to discriminate between the presence and absence of an Earth-strength (0.5 G) magnetic field and that successful discrimination was accompanied by fluttering (hovering, short flights) of the birds during the testing. If muscle activity of the sort normally executed by the bird during flight is required for the detection of magnetic stimuli, then the rather enigmatic results of Bookman's experiments would be readily explained.

It has not escaped our notice that our proposed mechanism may be relevant to the claim that positive dowsing responses in humans, indicated by the sudden flicking of a forked stick or the swinging of a pair of L-shaped rods, are correlated with relatively small changes in the local magnetic field[25-28]. As the dowsing instruments are held in such a way that the slightest movement of the wrists or forearms will be amplified into an appreciable movement of the stick or rods, a magnetically sensitive muscle receptor could conceivably give rise to muscular movement sufficient to produce the classic dowsing responses.

Table 1 Inducible magnetic remanence in the head and neck musculature of pigeons and white-crowned sparrows

	Head (e.m.u.)	Neck musculature (e.m.u.)
Pigeon	$1-7 \times 10^{-6}$ (19)	$1-15 \times 10^{-6}$ (19)
White-crowned sparrow	$2-4 \times 10^{-6}$ (2) 6×10^{-7} (5)	$1-8 \times 10^{-6}$ (7)

The numbers of birds which were found to have the various remanence values are shown in parentheses. For comparison with neck muscle specimens, comparably sized specimens of pectoral muscle and associated fascia from both pigeons and white-crowned sparrows had inducible magnetic remanences of less than 6×10^{-7} e.m.u. The noise level of the magnetometer was about 5×10^{-8} e.m.u.

Evidence for fixed charge in the nexus

Peter R. Brink & Maynard M. Dewey

Department of Anatomical Sciences, School of Basic Health Sciences,
Health Sciences Center, State University of New York at Stony Brook,
New York 11794

The nexus or gap junction has been characterized as a low-resistance junction as well as a highly permeable junctional membrane to many molecules[1-6]. The transfer of electrical current from one cell interior to another, the aqueous solubility of dyes used to trace cell to cell communication and the fact that these molecules move across the nexus more rapidly than the plasma membrane[4-10] have led to the hypothesis of an aqueous channel in the junction. Both Ca^{2+} (ref. 11) and H^+ (ref. 12) are thought to alter nexal membrane conductance, and a voltage-sensitive gate has been demonstrated within the junction[13]. Recently, Flagg–Newton *et al.*[14] have concluded that mammalian junctions may contain fixed charge or be of smaller diameter than arthropod junctions. Here, we have investigated these alternatives by examining the permeability of nexuses of septa of the median giant axon of *Lumbricus terrestris*[1,15] with various derivatives of fluorescein. Both carboxyfluorescein and aminofluorescein were found to have depressed permeabilities relative to their predicted permeabilities based on molecular size and weight (MW). Fluorescein diffusion was significantly suppressed in axons pre-injected with aminofluorescein but carboxyfluorescein had no such effect (Table 1). These data suggest the existence of fixed anionic charge within the nexal channel which may have affinity for amino groups.

Figure 1*a* and *b* illustrate the propagation of action potentials at the septa. The microelectrodes were 500 μm from the septum on either side; the position of the septum was delineated by a fluorescein injection. The action potential propagated across the septum at 8.0 m s^{-1}. Figure 1*c* shows the conduction of an action potential along the same axon in the absence of a septum. Here the conduction velocity was 25 m s^{-1}. The microelectrode separation was 1 mm. The velocity of the propagated action potential across the septum is reduced to 32% of the velocity measured along the axon. Note the slight loss in amplitude of the action potential after it has traversed the septum. Propagation of an action potential in either direction showed the same loss in amplitude. In Fig. 1*c* no loss in amplitude is observed when the action potential is conducted along the axon. The introduction of carboxyfluorescein, aminofluorescein or any of the halogen derivatives did not increase the time delay at the septum. Nexal membrane conductance was measured in the presence of carboxyfluorescein and aminofluorescein, and no statistically significant alteration in conductance was observed over controls[4].

Figure 2 illustrates the nexal permeabilities of various molecules plotted as a function of their widest dimension. With increasing size, molecules have more difficulty traversing the

junction. However, in the case of carboxyfluorescein and aminofluorescein this relationship does not hold. One possible conclusion is that the extra carboxyl and amino groups are interacting electrostatically with fixed charge in the nexal pore, resulting in decreased junctional permeability for those molecules. The hydration radius of the two molecules would be expected to be greater than that of fluorescein by virtue of their greater polarity[16] and this may in part explain their suppressed permeabilities. It must be remembered that all the probes to a greater or lesser degree are also hydrated. In contrast to carboxyfluorescein and aminofluorescein, tetrachlorofluorescein permeability on the basis of size (1.0 nm) and MW (471) would have a predicted permeability similar to those of dibromofluorescein or diiodofluorescein. Data given here show the permeability to be between those of dibromofluorescein and diiodofluorescein. The data in Fig. 2 also suggest a functional channel diameter of 1.2 nm.

Aminofluorescein binds to cytoplasmic proteins[1], and affinity for cytoplasmic proteins in part explains the suppressed permeability of aminofluorescein. It may also have an affinity for membrane proteins. However, carboxyfluorescein has little binding affinity for cytoplasmic proteins (Table 1). For

Aminofluorescein
Fig. 1*a* An action potential recorded by two microelectrodes 1 mm apart with a septum between. The amplitude of the action potential is decreased slightly on the 'postsynaptic side' of the septum. The time delay across the septum was the same regardless of the direction of action potential propagation. Microelectrode resistance varied from 20 to 40 M Ω. Dye injections were done to confirm septum position. Dye was injected by applying hyperpolarizing current pulses for 15–30 min. *b*, As in *a* except 100 μs cm^{-1}. The conduction velocity in the region of the septum was 8 m s^{-1}. *c*, An action potential recorded between two microelectrodes 1 mm apart with no septum between. Note that the action potential shows no alteration in amplitude. The conduction velocity in the septum-free region was 25 m s^{-1}. Aminofluorescein contains an amine group in the γ position relative to the primary carboxyl group. Carboxyfluorescein substitutes a carboxyl group for the amine.

carboxyfluorescein, its extra electronegativity can be hypothesized to cause the molecule to experience increased repulsive forces in the region of the nexal channel, hindering its flux across the nexus. It can be speculated that aminofluorescein has a suppressed flux because the amine group is interacting with an anionic site in the junctional channel itself, but its size does not allow complete blocking of the channel.

Aminofluorescein or carboxyfluorescein was pre-injected into an axon using the method reported by us[1]. Because both molecules diffuse across the septa slowly, within an hour only small or trace amounts of dye had traversed the septum into adjacent cells. Within that hour, fluorescein was injected (15 min) and post-injection photographs were made at 5-min intervals for 15 min after fluorescein injection. A photograph of the pre-injection of aminofluorescein or carboxyfluorescein was made immediately after its injection. The densitometric tracing of the pre-injection was subtracted from subsequent densitometric tracings made following fluorescein injection[1]. Aminofluorescein significantly reduces fluorescein permeability whereas carboxyfluorescein has no such effect (Table 1). If there was significant diffusion of aminofluorescein or carboxyfluorescein into adjacent cells, it would result in an apparent elevation of the permeability, not a suppression of it.

No rectification is seen across the septum with propagated action potentials or with applied current pulses[4]. Likewise, no preferred diffusion or polarity was observed for any of the dyes. The nexal pores discriminate on the basis of charge and size but not with respect to the direction from which the molecule approaches and crosses the junction. If the nexal membrane is assumed to have a transnexal potential of 0, then the fixed charge could be placed near the cytoplasmic openings or anywhere along the interior of the channel and no rectification would be observed[17].

The resistance for the earthworm septal membrane is $4 \times 10^4\,\Omega$ (ref. 4). Electron microscopic data have revealed that the septa contain nexuses over 4–5% of their surfaces[1], with a total of 3×10^6 particles per septum. Assuming that all the nexal channels are in parallel and similar in size, the resistance of each channel is $1.2 \times 10^{11}\,\Omega$ or 8 pS. However, assuming the channel is 1.5 nm in diameter and filled with axoplasm having a resistivity of $200\,\Omega$ cm (r_a), the channel resistance (R_p) would be $2.3 \times 10^{10}\,\Omega$ or 43 pS using the equation

$$R_p = r_a L / A \qquad (1)$$

where L and A symbolize length and cross-sectional area of the channel, respectively. The conductance of a single potassium

Fig. 2 Nexal membrane permeability plotted against the widest dimension of the molecules. Carboxyfluorescein (□) and aminofluorescein (▽) are the only molecules that do not fit the general relationship of decreasing P_n with dimension or as MW increases for anionic molecules[1]. The permeabilities of fluorescein (△), dichlorofluorescein (▲), dibromofluorescein (●), diiodofluorescein (○) and tetrabromofluorescein (■) were taken from ref. 1. The permeabilities of carboxyfluorescein, aminofluorescein and tetrachlorofluorescein (▼) were computed using the same methods as in ref. 1. Carboxyfluorescein contains an extra negative charge at physiological pH whereas aminofluorescein exists as a zwitterion. Even with these additional groups the widest dimension of the derivatives is the same as fluorescein (9.5 Å), assuming no hydration radius. The carboxyl group of fluorescein has a $pK = 3$–4 (ref. 20). Tetrabromofluorescein has a $pK = 5$ (ref. 21). Aminofluorescein would have a $pK = 3$–4 while the amine group would be assumed to have a $pK = 10$. The conductance of the junction in the presence of the halogen derivatives fell within the range of junctional conductance with none of the fluorescent probes present. Permeabilities not listed in Table 1 are given in ref. 1.

channel was estimated by Cole[18] from $1/f$ noise of hyperpolarized node membranes to be 0.5 pS. The sodium channel conductance has been given a similar value[19]. The diameter of the potassium channel is thought to be 0.3–0.4 nm. Using equation (1), where $r_a = 200\,\Omega$ cm and $L = 10.0$ nm, the single channel conductance is 2.5 pS. The lower conductance value can be attributed to electrostatic forces acting over molecular distances in the potassium channel and nexal membrane channel. The data presented here therefore suggest the existence of an anionic site within the nexal membrane channel.

Table 1 The influence of aminofluorescein on nexal membrane permeability

Dye	Permeability (cm s⁻¹)	Standard deviation (n)	Cytoplasmic binding
Fluorescein	5.4×10^{-5}	2.1×10^{-5} (10)*	
Aminofluorescein + fluorescein	2.2×10^{-5}	1.8×10^{-5} (11)*	
Carboxyfluorescein + fluorescein†	4.6×10^{-5}	1.3×10^{-5} (4)	
Aminofluorescein	6.0×10^{-7}	3.0×10^{-7} (8)	
Carboxyfluorescein	5.6×10^{-6}	3.0×10^{-6} (6)	6.8%
Tetrachlorofluorescein	2.1×10^{-5}	1.5×10^{-5} (4)	4.0%

Cytoplasmic binding was measured by the method given in ref. 1. The ratio of protein (cytosol) to dye was 10 to 1 assuming the average protein/MW was 10^4–10^5. The control permeability value for fluorescein in the absence of other dyes was taken from ref. 1. Aminofluorescein was injected into an axon followed by a fluorescein injection. The aminofluorescein injection was accomplished by applying a hyperpolarizing pulse of 20 nA amplitude, 100 ms duration, every 150 ms for 20 min. The fluorescein injection followed immediately with the same conditions. The pH of the electrode solutions was 8.2. Permeability was calculated by the method reported by us[1]. Aminofluorescein diffuses at such a slow rate that only trace amounts appear in the adjacent cell over an hour, allowing fluorescein to be injected (15 min) and photographs of subsequent fluorescein diffusion to be made at 5-min intervals for 15 min. Densitometric tracings were made of negatives and permeability calculated. Each photographic exposure was 40 s.
* Student's t-test comparison between fluorescein permeability and fluorescein permeability with a pre-injection of aminofluorescein. $P > 0.01$.
† Carboxyfluorescein was pre-injected using the same conditions as aminofluorescein followed by fluorescein injection. Fluorescein permeability and fluorescein permeability of carboxyfluorescein-injected axons were statistically insignificant.

Allergic encephalomyelitis induced in guinea pigs by a peptide from the NH₂-terminus of bovine P₂ protein

Steven W. Brostoff, James M. Powers & Michael J. Weise

Departments of Neurology and Pathology, Medical University of South Carolina, Charleston, South Carolina 29403

Experimental allergic neuritis (EAN) is an inflammatory demyelinating disease of the peripheral nervous system (PNS) first described by Waksman and Adams[1,2] in rabbit, guinea pig and mouse after injection of PNS antigen in Freund's complete adjuvant. In rabbit and mouse, the histological lesions were confined to the PNS but the guinea pig reacted curiously to PNS antigens by developing lesions in the central nervous system (CNS) as well as the PNS. Experimental allergic encephalomyelitis (EAE), the CNS counterpart of EAN, is known to be a response to CNS myelin basic protein. In early experiments[3,4], basic proteins from PNS myelin also produced a disease in guinea pigs characterised by CNS lesions. Characterisation of the proteins of PNS myelin demonstrated the presence of a basic protein (P₁) which was similar to the encephalitogenic basic protein of CNS myelin[5]. At first it seemed that the CNS lesions were being caused by this (P₁) protein. However, immunological studies from our laboratories suggested that when guinea pigs were sensitised to PNS myelin, the resulting lesions were a response to the small PNS myelin basic protein (P₂) and not to the P₁ protein[6]. In a preliminary report[7], we indicated that a peptide fraction derived from the P₂ protein could produce a disease in guinea pigs characterised by CNS lesions. Sequence studies under way in our laboratory now enable us to report that this response is being caused by a tryptophan-containing 20-residue peptide (CN3) derived from the NH₂-terminal segment of the bovine P₂ protein.

Bovine P₂ protein prepared from spinal nerve roots[8] has three methionine residues. Treatment of P₂ protein with CNBr results in four peptide chains, two of which remain covalently linked by an interchain disulphide bond. These chains consist of a peptide of 20 amino acids from the NH₂-terminus (CN3), a peptide of approximately 88 residues located internally (CN1), and the disulphide-linked dipeptide (CN2) representing the COOH-terminal 18 amino acids[9]. The sequence of the NH₂-terminal 65 residues which include CN3 has been reported[10].

In early experiments[11], P₂ protein (55 mg) was digested with CNBr (in 3.0 ml 70% formic acid) and the resulting peptides were separated by chromatography on a column (1.5 × 69 cm) of

Fig. 1 Sequences of the encephalitogenic determinant of bovine CNS myelin basic protein and peptide CN3 of bovine PNS myelin P₂ basic protein.

Sephadex G-50. The column was equilibrated and eluted with 0.1 M acetic acid at 35 ml h⁻¹; 3.0-ml fractions were collected. Only two main peptide-containing peaks were isolated. The peak appearing in the void volume (fractions 10–35) was designated fraction I and contained only the large internal peptide CN1. The second peak (fractions 38–43) was designated fraction II and was later shown to be a mixture of peptides CN2 and CN3. Each of these fractions was tested for its ability to produce disease in guinea pigs (Table 1). Of the two, fraction II clearly contained a disease-inducing site for guinea pigs, and produced a response characterised by strong clinical symptoms (at 75 μg dose) and histological lesions in the CNS characterised by unusually large numbers of plasma cells in the infiltrates as compared with either EAE or EAN.

In later experiments[9], the peptides resulting from CNBr digestion of the P₂ protein were separated by chromatography on G-25, which allowed isolation of CN2 and CN3. To establish which of the two contained the disease-inducing site, both were tested at two doses in guinea pigs. The data in Table 1 suggest that the determinant for disease induction in the guinea pig resides in the NH₂-terminal 20 amino acids of P₂ protein that comprises peptide CN3. The response in one of the three guinea pigs sensitised with CN3 also resulted in histological lesions in the CNS characterised by infiltrates containing unusually high numbers of plasma cells.

Because P₁ is encephalitogenic[12], the question of contamination of peptides derived from P₂ with the encephalitogenic determinant of P₁ must be considered. Our P₂ preparation is

Table 1 Disease-inducing properties in guinea pigs of CNBr peptides derived from the basic P₂ protein

Antigen	Dose (μg)	No. of animals tested	No. with clinical signs (day of onset)	No. with perivascular infiltration (severity) CNS	Histology PNS	No. with demyelination CNS	PNS
Fraction I (CN1)	50	3	0	2 (+/−)	0	0	0
Fraction II	75	4	4 (12, 12, 14, 19)	4 (++)*	0	4	0
	50	4	1 (15)	4 (+/− to +)*	0	2	0
CN2	75	2	0	0	0	0	0
	25	3	0	0	0	0	0
CN3	75	3	1 (15)	3 (+/− to +)	0	1	0
	25	3	0	2 (+/− to +)	0†	2	0

Each animal was injected into each hind footpad with 0.1 ml (0.2 ml per animal) of an emulsion containing equal volumes of antigen dissolved in saline and Freund's complete adjuvant (Difco, H37 ra). Clinical signs and histology were evaluated as described previously[11]. Perivascular infiltration was graded in severity according to the system of Alvord and Kies[15].
* Plasma cells were unusually prominent in the mixed cellular infiltrates.
† A small focus of perivascular lymphocytes was observed in the nerve root of one animal.

assessed to be free of contamination with the encephalitogenic P_1 protein by its failure to produce allergic encephalomyelitis when injected into rabbits, even at 5 mg doses[8]. It is even more unlikely that CN3 is contaminated with the encephalitogenic determinant from P_1 because, after cyanogen bromide cleavage of P_1, this determinant would remain in a large (146 residue) peptide which would easily separate from the small (20 residue) CN3 during subsequent purification by column chromatography and paper electrophoresis. There is no evidence that CN3 contains additional peptides even after tryptic digestion[9].

CN3 apparently contains the antigenic determinant in bovine P_2 responsible for producing a neurological disease in guinea pigs characterised by perivascular infiltration and demyelination in the CNS. The encephalitogenic determinant for EAE in the guinea pig has been shown[13] to be a peptide (residues 114–122) of the bovine CNS myelin basic protein containing that molecule's only tryptophan residue (see Fig. 1). Tryptophan is essen-

tial for disease induction in conjunction with a Gln-Lys (or Gln-Arg sequence)[14]. By way of comparison, peptide CN3 (residues 1–20 of the bovine PNS myelin basic protein) also contains a single tryptophan, an Asn-Lys sequence and produces an EAE-like disease in guinea pigs. One might speculate that the chemical requirements of a determinant for EAE are not exact and that the presence of tryptophan, asparagine and lysine in CN3 may be sufficient for its disease induction. One might further speculate that the reason for the required large dose of this peptide and resultant milder disease (compared with the encephalitogenic peptide of CNS myelin basic protein) is that the relative locations of tryptophan and lysine residues are different.

Structure of slow-reacting substance of anaphylaxis from guinea-pig lung

Howard R. Morris*, Graham W. Taylor*, Priscilla J. Piper† & John R. Tippins†

* Department of Biochemistry, Imperial College, South Kensington, London SW7, UK
† Department of Pharmacology, Institute of Basic Medical Sciences, Royal College of Surgeons, Lincolns Inn Fields, London WC2, UK

Slow-reacting substance of anaphylaxis (SRS-A) is a primary mediator of immediate-type hypersensitivity reactions, probably having a major bronchoconstrictor role in asthma. Although it was discovered some 40 years ago[1] the structure has remained unknown. Major advances in purification technology[2,3] have resulted in the preparation of chemically pure material, and the demonstration that SRS-A has a characteristic UV spectrum[2] has enabled a correlation to be made between biological activity and a structural moiety in the molecule. Previous studies have indicated that SRS-A from guinea pig lung is derived from arachidonic acid[4]; data, based on the chemical and enzymatic destruction of biological activity, have indicated the presence of α-amino, carboxyl and thioether functions[3]. We now report the first spectroscopic (mass spectrometric) and analytical protein chemical data on intact SRS-A which allows us to define unequivocally the complete covalent structure of this immunologically generated material as the novel peptidolipid 5-hydroxy-6-cysteinyl glycinyl-7, 9, 11, 14-eicosatetraenoic acid. The structure determined is identical to that which we have assigned to the major non-immunologically generated slow-reacting substance (SRS) obtained from rat basophil leukaemia (RBL-1) cells[5], but different from that of a recently synthesized chemical with SRS-like activity[6] whose structure was modified from an earlier, incorrect structure of the natural product[7].

SRS-A was prepared from immunologically challenged lungs of guinea pigs sensitized to ovalbumin[8] and purified to homogeneity by our previously published methods[2,3] (Fig. 1); the difficulties associated with the purification of vanishingly small amounts of SRS-A were overcome by use of the procedures shown in Fig. 1, including the introduction of reverse-phase HPLC[2,8], with its attendant high resolution separative capabil-

ity. It was shown that the essentially homogeneous material prepared, had a characteristic UV spectrum[2] (Fig. 2) (λ_{max}^{MeOH} 280 nm) and this discovery has been very useful in locating SRSs[8,9] and providing a cross-correlation between biological activity on the guinea pig ileum and a chemical entity, the conjugated triene attributed to this chromophore[8].

In the final purification (Fig. 1) the active SRS-A fraction from HPLC-1 separated[3] into four UV-absorbing compounds (Fig. 2); compound I (λ_{max} 280 nm) fulfills all the criteria for SRS-A[8]; compound II has a similar UV spectrum, but is shifted hypsochromically by 2–3 nm (λ_{max} 278 nm). This material has apparently reduced biological activity, probably corresponding to a *cis-trans* isomerization of one of the double bonds in SRS-A; compound III (λ_{max} 270 nm) does not contract the guinea pig ileum and we have previously shown this to be 5, 12 dihydroxy-6, 8, 10, 14 eicosatetraenoic acid[3], compound IV is probably related to compound III by a similar isomerization to that observed for compounds I and II.

The precursor role of arachidonic acid has been indicated by data on the potentiation of SRS-A from guinea pig chopped lung[4]. Destruction of biological activity by soya bean lipoxygenase (w6 specificity) has shown the presence of a 1—4 *cis* pentadiene unit in the SRS-A molecule[10].

Fig. 1 The extraction and purification of SRS-A from guinea pig lung[3,8]. At all stages of purification SRS-A was monitored by bioassay on guinea pig ileum (in the presence of mepyramine and hyoscine).
Fig. 2 The full UV spectra of compounds 1–IV isolated by purification of the active fraction from immunologically challenged guinea pig lung.

Chemical inactivation data studied by monitoring the loss of biological activity after brief exposure of SRS-A to various reagents indicates the presence of certain functional groups[3]— α-amino (short acetylation), thioether (cyanogen bromide) and carboxyl (methylation). The presence of the α-amino group thus postulated in SRS-A, was used to provide a marker label in the mass spectrometric work (see below), thus enabling location of the relevant SRS-A signals and differentiation from those signals arising from background contribution.

Amino acid analysis of the peak tubes of biological activity showed the presence of the amino acids, glycine and cysteine. Tubes corresponding to compound III were devoid of amino acids above background level. To determine the sequence of the two amino acids, the active sample was dansylated, hydrolysed and the dansyl derivative examined by TLC[11]. The results showed a fluorescent spot arising from a single N-terminus, moving more slowly than dansyl glycine in all dimensions; dansyl cysteine prepared as a standard in the presence of arachidonic acid gave a spot with identical mobility.

Derivatives for mass spectrometry were chosen to improve the volatility of SRS-A in a manner which would not affect the basic structural units, (1) by using reactions previously well studied in protein chemistry[12], and (2) by rejecting those reactions which caused changes in either UV absorbance or λ_{max} of the triene chromophore.

To monitor the variables of absorption phenomena, reagents and reaction conditions used in the final stages of the structure elucidation, a slow reacting substance (SRS), whose structure we have previously defined[5], was prepared from rat basophil leuk-aemia cells (RBL-1).

The RBL-1 SRS had a similar elution position in the HPLC-2 step (Fig. 1), and identical pharmacological and physicochemical properties to SRS-A. The full UV spectrum of the SRS-A used for the mass spectrometric experiments was determined, (600 U, A = 1.3), and a deliberately smaller amount of RBL-1 SRS was taken for the control experiments, corresponding to 0.75 of the SRS-A UV absorbance. RBL-1 SRS was derivatized using acetic anhydride in the acetylation step, whereas the guinea pig lung SRS-A was acetylated using a 1:1 mixture of acetic anhydride and d_6 acetic anhydride to provide the mass spectrometric marker. The other derivative-forming steps were identical, being esterification in ethereal diazomethane (30 min) and trimethylsilylation in pyridine/bis (trimethylsilyl) trifluoroacetamide/trimethylchlorosilane (1:6:1 30 min).

Figure 3 shows the mass spectrum produced at 240 °C from guinea pig SRS-A (Fig. 3a) compared with that produced from the RBL-1 control (Fig. 3b) and with our previously reported spectrum of RBL-1 SRS, from which its structure was deduced[5] (Fig. 3c). The spectra unequivocally show that SRS-A from guinea pig lung is identical to that of RBL-1 SRS in covalent structure, as the same fragment ions are observed in the same relative abundance ratios at an identical ion source temperature.

Figure 3 also illustrates the considerable difficulty of determining structure on the small quantity of SRS-A available from lung, for, in contrast to our previous work on RBL-1 SRS, at this lower level the molecular ion was not observed for either SRS-A or the RBL-SRS control. The absence of the molecular ion does not in any way affect the interpretation, as the full structure is found by combining the information from the fragment ions formed. For example, in Fig. 3a, m/e 607 corresponds to $M^+ - OCH_3$ (containing both the peptide and lipid moieties), m/e 548 corresponds to $M^+ - TMSOH$ (showing the presence of a hydroxyl group), m/e 404/405 and m/e 314/315 (−TMSOH) define the lipid portion of the molecule and m/e 203 defines the substitution of the hydroxyl at C-5. Confirmatory experiments on the signals shown in Fig. 3, involving further isotopic labelling (for example, d_9 TMS), and high resolution mass measurements enable us to define rigorously the structure of SRS-A from guinea pig lung as the novel peptidolipid 5-hydroxy-6-cysteinyl glycinyl-7, 9, 11, 14-eicosatetraenoic acid (Fig. 4).

Using the same arguments as previously described in the structure elucidation of RBL-1 SRS[5], we can position the double bonds in SRS-A and define the substitutions of the tetraene (C_{20}: 4-eicosatetraenoic acid) at C-5 (hydroxyl) and C-6 (thioether). Importantly, the mass spectrum also shows what is not present in the structure; for example, we can say that the SRS-A does not contain a glycine-amide which would be difficult to discount by chemical or enzymatic methods. Similarly, we can say that SRS-A does not contain a sulphate moiety, widely expected from the results of destruction of biological activity by aryl sulphatase, reported in the literature[8,13]. It is of some interest that the structure we propose here for SRS-A derived from immunologically stimulated lung is identical to that which we have previously described for SRS released by non-immunological stimulation from malignant basophils. Furthermore, this structure could be biosynthetically derived by an intriguing combination of the lipoxygenase metabolism of arachidonic acid[14] with the glutathione detoxification pathway[15] involving nucleophilic attack of the
Fig. 3 (a), The electron impact mass spectrum of the trimethylsilyl (TMS) ether of the N-acetyl (CH_3CO/CD_3CO 1:1) methyl ester of SRS-A from guinea pig lung. cysteinyl sulphur on a 5,6-oxido-eicosatetraenoic acid. Interestingly, we find no evidence in either the natural SRS-A reported here or our previous SRS preparations[5], for a glutathionyl structure such as that recently described for a synthetic substance possessing SRS-like pharmacological and chromatographic properties[6]. The cysteinyl glycine structure reported here (Fig. 4) is rigorously defined for both SRS-A and SRS[5] from the mass spectrum (Fig. 3). We discount the possibility of having lost a major component of any putative glutathionyl SRS-(A) during purification, because (1) all fractions from the various column eluates were screened for biological activity, and (2) where partitioning took place (that is, at the charcoal absorption and ether extraction steps) no biological activity was found in the aqueous fractions. Despite yields of > 75% at these stages, this does not preclude either a minor component having adsorbed to charcoal (unlikely for a more polar substance) or enzymatic processing (either physiologically significant or otherwise) of compounds in the perfusate. In any event, the structure identified here for lung SRS-A is the major biologically active compound studied by pharmacologists and while the detailed enzymatic steps in the biosynthesis of SRSs are under investigation, it is, however, possible that SRSs of different cellular origins may have different structures or metabolism.

The first demonstration, given here, that a mass spectrum can be produced from undegraded SRS-A, taken together with our previous work on SRS[5], forms the basis for future precise identifications of all these substances, using the readily formed derivatives suggested; the mass spectrum can also be used in quantitative studies.

This definition of the structure of guinea pig lung SRS-A and the likelihood that human SRS-A has the same structure[8], open the way towards new and enlightened study into the pathology and therapy of asthma and other allergic diseases. It will also lead to exploration of the physiological roles of SRS-A, 5,12-dihydroxyeicosatetraenoic acid and the other UV absorbing lipoxygenase products.

Chemical inducers of differentiation in Friend leukaemia cells inhibit lymphocyte mitogenesis

K. H. Stenzel, R. Schwartz, A. L. Rubin & A. Novogrodsky

Rogosin Kidney Center, Departments of Biochemistry, Medicine and Surgery, Cornell University Medical College, New York, New York 10021

Several phorbol esters, the potent tumour-promoting agents[1] isolated from croton oil, induce proliferation of human lymphoctyes[2,3] and enhance the mitogenic effect of lectins on bovine lymphocytes[4]. While studying the mitogenic properties of one of these agents, phorbol myristate acetate (PMA), we found that dimethyl sulphoxide (DMSO), frequently used as a solvent for PMA, markedly inhibits PMA-induced mitogenesis at DMSO concentrations that have little effect on phytohaemagglutinin (PHA)-induced responses. DMSO, as well as a variety of other organic compounds, induce erythroid differentiation in Friend leukaemia (FL) cells[5-9]. Phorbol esters, on the other hand, are potent inhibitors of both spontaneous and induced cellular differentiation[10-13]. We therefore investigated the relationship between the potency of compounds to induce erythroid differentiation in FL cells and their potency to inhibit lymphocyte proliferation induced by PMA and other mitogens. We report here that many of the compounds that induce erythroid differentiation in FL cells are similar to DMSO in selectively suppressing PMA-induced lymphocyte mitogenesis.

The effect of a variety of organic solvents on the proliferation of human lymphocytes stimulated with either PMA or PHA is shown in Table 1 and compared with their reported effects on the differentiation of FL cells. Compounds that induce erythroid differentiation in FL cells inhibit lymphocyte mitogenesis, whereas compounds inactive in inducing erythroid differentiation in FL cells do not inhibit lymphocyte mitogenesis. The concentrations of those compounds which suppress lymphocyte proliferation are in the same range as those reported to induce differentiation. Among the compounds outlined in Table 1, butyric acid, previously reported to inhibit lymphocyte activation[14], is the most potent inducer of erythroid differentiation[6] and is also the most active inhibitor of PMA-induced mitogenesis. However, compounds which are structurally related to butyric acid, but which do not induce erythroid differentiation,
Fig. 1 Effect of butyric acid (●), DMSO (△), isobutyric acid (○) and α-aminobutyric acid (□) on the proliferative response of a human one-way mixed lymphocyte culture. The culture was done as previously described[26]. This experiment is typical of three additional studies. Results are presented as the mean ±s.e.m. of quadruplicate cultures.

Table 1 Inhibition of lymphocyte mitogenesis by compounds which induce erythroid differentiation in FL cells

Compound tested	Concentration range (mM) resulting in 50% inhibition of ^{3}H-thymidine incorporation		Concentrations (mM) reported to induce maximum erythroid differentiation in FL cells
	PMA-induced responses	PHA-induced responses	
Polar organic solvents			
Dimethyl sulphoxide	60	>210	280(7)*, 280(9), 70–300(6)
Dimethylformamide	75	120	60(11), 150(7)
N,N-dimethylacetamide	5–10	25	20(9), 30(7)
Short-chain fatty acids			
Propionic acid	1–1.5	10	2(6)
n-Butyric acid	0.1–0.4	1.4	1–2(6), 1(9)
n-Valeric acid	1.6	>4.0	2(6)
Caproic acid	>10	>10	Inactive(6)
Butyric acid analogues			
Isobutyric acid	4–5	>10	30(24)
β-OH-butyric acid	>10	>10	Inactive(6)
γ-OH-butyric acid	>10	>10	
α-Amino-butyric acid	>10	>10	
β-Amino-butyric acid	>10	>10	
γ-Amino-butyric acid	>10	>10	Inactive(6)
Purine analogues			
Hypoxanthine	1–2	>5.0	3.7(15)
1-Methylhypoxanthine	0.5–1.0	3–5.0	3.3(15)
Xanthine	>5.0	>5.0	Inactive(15)
Allantoin	>5.0	>5.0	Inactive(15)

Human peripheral blood mononuclear cells were obtained from normal subjects as previously described[25]. Final cell preparations (10^6 cells ml^{-1}) were suspended in RPMI-1640 medium containing 5% heat-inactivated fetal calf serum and supplemented with penicillin (100 U ml^{-1}) and streptomycin (100 μg ml^{-1}). Cells were distributed (0.2-ml aliquots) in flat-bottom microwells, the mitogens (PMA 10 ng ml^{-1} or PHA 2 μg ml^{-1}) and compounds to be tested were added, and the cells were then incubated at 37 °C in a 95% air, 5% CO_2 atmosphere for 72 h. ^{3}H-thymidine incorporation (2 μCi per well) into DNA was determined during the final 52–72 h of incubation. The extent of proliferation as determined by ^{3}H-thymidine incorporation in the absence of the test compounds was: PMA (n = 76) 91,169 c.p.m. (s.e.m. = ±2,312), PHA (n = 78) 133,260 c.p.m. (s.e.m. = ±4,012). *Numbers in parenthesis indicate reference from which data were obtained.

do not inhibit lymphocyte proliferation (Table 1). DMSO and butyric acid inhibit PMA-induced morphological transformation and ^{3}H-leucine, ^{3}H-uridine and ^{3}H-thymidine incorporation.

The organic compounds do not inhibit lymphocyte mitogenesis by nonspecific effects on cell viability as directly assessed by the trypan blue exclusion assay. Moreover, following a 2-day incubation with 0.5–1.0 mM butyric acid or 70–140 mM DMSO, lymphocytes are capable of responding to mitogens when the organic solvents are removed by washing the cells. We also found that the organic solvents are most inhibitory when added early in blastogenesis and are much less effective when added 24 h after the mitogenic stimulus. Lymphocyte responses induced by other mitogens (concanavalin A, soybean agglutinin, peanut agglutinin and treatment with neuraminidase and galactose oxidase) have the same resistance to inhibition by DMSO and butyric acid as responses induced by PHA. Lymphocyte activation induced by allogeneic cells in one-way mixed lymphocyte cultures, on the other hand, are as sensitive to suppression by DMSO and butyric acid as are responses to PMA (Fig. 1).

Hypoxanthine and 1-methylhypoxanthine, both known to induce FL cell differentiation[15], inhibit mitogenic responses to PMA and, to a lesser degree, responses to PHA. Xanthine and allantoin, on the other hand, are inactive in both assays (Table 1). Haemin, another known inducer of FL cells[16], differs from the polar organic compounds in that it seems primarily to induce early events in differentiation[17] and does not inhibit FL cell division[18]. We found that haemin alone induces modest increases in ^{3}H-thymidine incorporation in human peripheral blood lymphocytes (Fig. 2). When cells are stimulated with PMA or PHA, haemin inhibits mitogenesis at approximately the same concentrations reported to induce FL cell differentiation (0.75–0.1 mM) (Fig. 2).
Fig. 2 Effect of haemin on the proliferative response of human peripheral blood lymphocytes (●), ^{3}H-thymidine incorporation (c.p.m. × 10^{-3} per culture), and on PMA (△) and PHA (○) induced ^{3}H-thymidine incorporation (% of control = % of ^{3}H-thymidine incorporation in cultures stimulated with the mitogen in the absence of haemin). Results are presented as the mean of duplicate cultures. Three additional experiments gave similar results.

These studies indicate that there is a remarkable parallelism between the potency of compounds to induce erythroid differentiation in FL cells and their potency to inhibit lymphocyte mitogenesis. Inducers of erythroid differentiation have multiple effects on FL cells[19] and it is unknown which of these effects are relevant to inhibition of mitogenesis. A prominent effect of the polar organic solvents is to decrease the fluidity of lipid membranes[20]. The phorbol esters, on the other hand, increase the fluidity of cell membranes[21], as do other mitogens[22]. It is possible, then, that the inducers of FL cell differentiation inhibit lymphocyte mitogenesis by interfering with the mitogenic signal at the membrane level. The selective inhibitory effect of the various inducers on lymphocyte responses to different stimuli might be due to different triggering signals induced by the different stimulatory agents, or to different subpopulations of lymphocytes responding to the different stimuli. An indication that PMA-responsive lymphocytes are distinct from those responding to PHA and concanavalin A was previously reported[23].

The chemical inducers of differentiation in FL cells constitute a new class of inhibitor of lymphocyte mitogenesis. Their potential use as immunosuppressive agents is now under investigation. A critical evaluation of the relationship between inhibition of lymphocyte mitogenesis and induction of differentiation should provide new insights into the mechanisms of these processes.

Levels of 2,3-diphosphoglycerate in Friend leukaemic cells

G. C. T. Yeoh

Department of Physiology, University of Western Australia, Nedlands, Western Australia 6009, Australia

Most cells are thought to contain trace amounts of 2,3-diphosphoglycerate (DPG), as it acts as a cofactor in the interconversion of 2-phosphoglycerate and 3-phosphoglycerate by the glycolytic enzyme phosphoglyceromutase. DPG is synthesized from 1,3-diphosphoglycerate by the action of diphosphoglycerate mutase. Lowry *et al.*[1] reported levels of 29 µmol DPG per kg wet weight brain tissue which is approximately 3 pmol per 10^8 cells, assuming that 1 g of brain tissue contains 10^9 cells. In contrast, erythroid cells contain 50–100 nmol DPG per 10^8 cells, depending on the species and the stage of development[2]. This is of the order of a 1,000-fold more DPG compared with non-erythroid cells. In red cells DPG concentration modulates the binding of oxygen to haemoglobin[3,4]. I show here that erythroid precurser cells also contain markedly raised levels of DPG.

The terminal stage of erythropoiesis is accompanied by the appearance of haem, globin, spectrin and carbonic anhydrase. There is evidence that the genes associated with these markers are expressed by virtue of a mitotic division[5]. Using Friend leukaemic cells (FLC) as a model of erythropoiesis[6], this laboratory has attempted to obtain markers which characterize early cells in the erythroid lineage by studying the uninduced FLC. This cell seems to be arrested at about the proerythroblast stage of red cell differentiation[7] unless it is induced to proceed further by a variety of polar compounds, generally dimethyl-sulphoxide (DMSO)[8].

Anticipating that these erythroid precursor cells would develop mechanisms for accumulating iron before haemoglobin synthesis, the level of transferrin receptors in uninduced FLC was measured. These receptors bind transferrin specifically and facilitate its internalization together with two atoms of iron per molecule of transferrin. Our study[9], and those of other laboratories[10,11], have shown that transferrin receptors are indeed present in uninduced FLC.

How iron is released from transferrin intracellularly is unclear. However, *in vitro* experiments using cell-free extracts have shown that DPG is able to mediate the release of iron from transferrin[12]. Therefore, it is possible that this process takes place in the intact cell. If so, it would be expected that, in addition to red cells and induced FLC, erythroid precursor cells and uninduced FLC would display levels of DPG significantly higher than that found in non-erythroid cells. The level of DPG measured fluormetrically[1] in uninduced FLC is 4.3 nmol per 10^8 cells (Table 1). This increases by about twofold after the cells are induced to differentiate by DMSO. In comparison, mouse red cells contain 81 nmol DPG per 10^8 cells. DPG in cultured embryonic mouse fibroblasts could not be detected using the standard assay, even after increasing the sensitivity of the assay 100-fold, that is, to the 10–50-pmol range. Similar results were obtained with cultured epithelial cells derived from embryonic rat hepatocyte cultures[13] and cultured human lymphocytes of the IM-9 line[14]. It is concluded that these cells contain < 10 pmol DPG per 10^8 cells. This is less than reported for brain tissue[1], but in those experiments no precautions were taken to

Table 1 DPG levels in Friend leukaemic cells

Cell type	DPG (nmol per 10^8 cells)	% Hb cells
FLC (0)	4.3 ± 0.5	0.3
FLC (3)	5.2 ± 0.4	29
FLC (6)	6.1 ± 0.3	90
FLC (9)	8.7 ± 0.2	82
Mouse RBC	81.1 ± 3.2	100
Mouse fibroblast	ND	0
Rat epithelial cells	ND	0
Human lymphoid cells (IM-9)	ND	0

FLC were cultured as previously described[9] in the presence of 1.86% DMSO for days indicated in parentheses. Duplicate estimations of DPG were performed on three cultures for each group and four samples for mouse RBC. Per cent haemoglobinized cells was determined by benzidine staining[19]. Between 5×10^7 and 10^8 cells were used for each sample. Cells were pelleted then washed twice with ice-cold balanced salts solution by centrifugation at 1,000g. The final pellet was sonicated in 100µl 0.5 N HClO$_4$, centrifuged at 4,000g for 10 min and the supernatant removed and neutralized with 100µl 0.5 M NaOH. Aliquots of between 10 and 40 µl were taken for DPG determination by the enzyme-coupled fluorometric method of Lowry *et al.*[1]. Each assay contained 5.2 nmol of NADH and the decrease in absorbance at 340 nm was measured in a Perkin Elmer fluorescence spectrophotometer model 240-A. DPG and NADH standards were incorporated in each set of determinations. Results are expressed as means ± s.e.m. DPG could not be detected (ND) in extracts of cultured embryonic mouse fibroblasts, rat epithelial cells of human lymphoid cells in spite of 100-fold increase in sensitivity over the standard assay. Therefore, these cells are estimated to contain less than 0.01 nmol DPG per 10^8 cells.

exclude possible contamination of samples with blood, whereas this is avoided in cultured cells. Reddy and Burns[15] have attempted to measure DPG levels in myocytes, hepatocytes and adipocytes of the rat and conclude that levels were undetectable. They were also unable to demonstrate the presence of 2,3-diphosphoglycerate mutase, the enzyme responsible for DPG synthesis.

These results indicate that erythroid precursor cells, as judged by the levels found in uninduced FLC, have at least a 1,000-fold more DPG than non-erythroid cells; for example, rat epithelial cells, human lymphoid cells or mouse fibroblasts. The small percentage (0.3%) of haemoglobinized cells in the uninduced culture cannot account for the relatively high levels of DPG found in the control culture. This result differs from those of Kabat *et al.*[16] and Scher *et al.*[17], who were unable to detect DPG in uninduced or induced FLC using the method of Maeda *et al.*[18] This may be explained by the greater than 100-fold increase in sensitivity of the method used in this study achieved by fluorometric measurement of NADH oxidation by enzyme-coupled assay in contrast to the spectrophotometric determination of inorganic phosphate liberated from DPG used in previous studies. After induction, when most of the FLC are haemoglobinized, there is only a small increase in DPG. The presence of DPG in uninduced non-haemoglobinized FLC suggests it is not one of the group of erythroid markers which appear at the terminal stage of erythropoiesis, as would be predicted if its only role in the red cell was to modulate the affinity of oxygen for haemoglobin. Its early appearance is consistent with the proposal that it may have a role in iron accumulation by the developing red cell and that it continues to accumulate during erythroid maturation.

Saccharin may act as a tumour promoter by inhibiting metabolic cooperation between cells

J. E. Trosko, B. Dawson, L. P. Yotti & C. C. Chang

Department of Pediatrics and Human Development, College of Human Medicine, Michigan State University, East Lansing, Michigan 48823

The possible role of saccharin in the carcinogenic process is, at present, still unclear. Carcinogenesis is a complex process involving, in many test systems, initiation and promotion phases[1]. Current evidence favours the hypothesis that initiation is due to a mutagenic event, while promotion (at least the early portion) is the result of epigenetic changes[2]. Although saccharin has been reported to be a weak mutagen in various *in vitro* test systems and a weak initiator in mouse skin[3-7], there is increasing evidence from *in vitro*, as well as *in vivo*, studies that it might act as a tumour promoter[8-13], rather than as a mutagen[14-19]. Recently, L.P.Y. *et al.*[20] and J.E.T. *et al.*[21] developed an *in vitro* assay to detect tumour promoters, which has been independently reported by Murray and Fitzgerald[22]. The assay is based on the principle that phorbol ester-type tumour promoters block 'metabolic cooperation' or a type of cell–cell communication between cells. We report here a series of experiments demonstrating the elimination of metabolic cooperation in the hypoxanthine guanine phosphoribosyltransferase (HGPRT) system in Chinese hamster V79 cells, indicating that saccharin shares properties similar to those of other known promoters.

In an attempt to examine the potential biological effects of saccharin in intercellular communication, we seeded a small number of HG-PRT$^-$ (6-thioguanine resistant) V79 cells in the presence of a large number of HG-PRT$^+$ (6-thioguanine sensitive) cells sufficient to reduce the recovery of the resistant cells via the mechanism of metabolic cooperation[23]. If the same experiment is conducted with the addition of 12-tetradecanoyl-13-phorbol-acetate (TPA) or a chemical with promoting properties, the reduction in the recovery of 6-thioguanine resistant cells is significantly prevented. Figure 1 depics the result of adding various concentrations of saccharin (Sigma, Lot 65C-0129) to this metabolic-cooperation assay. With saccharin levels

Table 1 Recovery of 6-thioguanine resistant cells in the presence of TPA, pure saccharin, impure saccharin and Sweet'N Low

No. of V79 cells (HG-PRT$^+$)	No. of 6-TG^r cells (HG-PRT$^-$)	Drug	Concentration	% Recovery
—	100	—	—	79.1
7×10^5	100	—	—	18.9
7×10^5	100	TPA	0.1 µg ml^{-1}	96.4*
7×10^5	100	Pure saccharin	3 mg ml^{-1}	40.2*
7×10^5	100	Impure saccharin	3 mg ml^{-1}	42.0*
7×10^5	100	Sweet'N Low	3 mg ml^{-1}	22.2
7×10^5	100	Sweet'N Low	5 mg ml^{-1}	23.6

* Treatment significantly increased recovery ($P < 0.01$) according to SNK test.

Fig. 1 Dose–response curve for the effect of saccharin on the inhibition of metabolic cooperation between 6-thioguanine sensitive and resistant Chinese hamster V79 cells. The shaded areas correspond to the mean recovery of 6-TG cells for the control and TPA-treated groups ±s.d. Wild-type s-TG^s cells and X-ray-induced 6-TG^r cells were grown in modified Eagle's medium supplemented with a 100% increase of non-essential amino acids, 1 mM sodium pyruvate and 5% fetal calf serum. Both cell lines were plated in 100-mm plates at the same time (7×10^5 6-TG^s and 100 6-TG^r), allowed to attach, and then treated with the TPA (0.1 µg ml^{-1}) or saccharin and 6-thioguanine (10 µg ml^{-1}). The medium was replaced after 3 days and 5 days with medium containing 6-thioguanine. After 7 days the colonies were fixed, stained with Giemsa and scored. The results are expressed as the percentage of plated 6-TG^r cells (determined by control plates containing 100 6-TG^r cells for each treatment) that formed colonies in the presence of the 6-TG^s cells. None of the saccharin doses decreased the colony-forming ability. All of these *in vitro* promotion assays are done with non-toxic concentrations of presumptive promoters.

above 2 mg ml^{-1}, there is a linear 'rescue' of 6-thioguanine resistant cells. Compared with TPA, the effect of saccharin on the inhibition of metabolic cooperation is weak. Whereas 0.1 µg ml^{-1} of TPA resulted in a four- to fivefold increase in the recovery of 6-thioguanine resistant cells, 5 mg ml^{-1} of saccharin caused only a twofold increase.

Since Wolff and Rodin[4] showed that both impure (lot S1022, Maumee process, Sherwin-Williams) and pure samples of saccharin induced sister chromatid exchanges, we performed an experiment to find whether this same impure saccharin and a commercial preparation (Sweet'N Low) would affect metabolic cooperation. Table 1 shows that both the impure and pure saccharin worked to block metabolic cooperation. Sweet'N Low failed to block metabolic cooperation, probably because only 4% of the mixture was saccharin (the maximum concentration of saccharin was 0.2 mg ml^{-1}).

The demonstration that the saccharin preparation seems to be a weak promoter of certain cancers and to block metabolic cooperation. Table 1 shows that both the impure and pure to other promoters suggests that, at least for rodents, it can influence tumorigenesis at a high concentration by affecting cell–cell communication rather than by mutating cells. The observation that sister chromatid exchanges are induced not only by known DNA damaging agents/mutagens[24], but also by a tumour promoter (TPA)[25] and anti-promoters raises some new and interesting problems related to both the mechanism of action of tumour promoters and the assays used to detect them.

Embryonal carcinoma stem cells lack a function required for virus replication

James W. Gautsch

Department of Cellular and Developmental Immunology, Research Institute of Scripps Clinic, 10666 N. Torrey Pines Road, La Jolla, California 92037

Embryonal carcinoma (EC) stem cells are thought to be equivalent to the ectoderm of the preimplantation mouse embryo because they share morphological, biochemical and antigenic properties[1,2]. These near diploid EC cells can be induced to differentiate into cell types of all three germ layers[1,2]. They also can take part in normal differentiation and contribute cells to many tissues in chimaeric mice derived from preimplantation mouse embryos injected with them[3]. The ability to restrict the growth of certain viruses is a distinguishing characteristic of EC cells[4–8], but it is intriguing that this restriction disappears after differentiation. The ability of EC cells to block totally productive infection by the highly infectious and oncogenic Moloney strain of murine leukaemia virus (M-MuLV) is remarkable, as virtually all other murine cells are permissive to the growth of this virus. Teich et al.[7] suggested that replication of M-MuLV in EC cells is blocked at some point after integration of proviral DNA into the cell's genome. Here I enquire into the dominant or recessive nature of the restriction, that is, do EC cells show transdominant inhibition of virus replication analogous to that imposed by interferon or the mouse Fv-I locus, or is the block to MuLV replication due to the lack of something in the EC cell? This report shows that the restriction of M-MuLV in EC cells can be overcome by fusion with permissive cells. The resulting complemented growth of M-MuLV in EC/permissive cell heterokaryons indicates that the restriction over M-MuLV is a recessive trait of EC cells and, therefore, defines a hitherto unknown host function that is vital to virus growth but missing in EC cells.

Virtually all permissive mouse cells (SC-1 and 129/Sv mouse embryo fibroblasts (MEF)) infected with M-MuLV formed syncytial plaques in an infectious-centre XC assay (Table 1a). Infected EC-A cells did not form plaques, indicating that pro-

geny virus was not produced. However, when EC-A cells were infected with M-MuLV and then fused with uninfected permissive cells, XC plaque formation was evident (Table 1b). This complementation of M-MuLV growth in infected EC-A cells was provided by fusion with uninfected SC-1 cells, 129/Sv secondary MEF, mink lung cells or rabbit epithelial cells. The latter two types complement M-MuLV growth although these mink and rabbit cells are themselves resistant to infection by M-MuL V (either because they lack surface membrane receptors[9] or because the virus cannot penetrate their plasma membranes). In the control, fusion of infected EC-A cells with uninfected EC-A cells did not result in XC plaque formation. The appearance of XC plaques did not result from free or EC-bound infectious virus because the addition of permissive cells to infected EC-A cells, without fusion, resulted in little, if any, plaque formation. Also, culture supernatants collected at various times before and after polyethylene glycol (PEG) fusion, and used to 'infect' SC-1 cells, were consistently negative for infectious plaque-forming virus. This was done to eliminate the

Table 1 Complementation of M-MuLV growth in EC-A cells

M-MuLV-infected cells*	Uninfected complementing cells	$\log_{10}$ ICPFU $ml^{-1\dagger}$ fused[‡]	not fused
a			
EC	—	<0.3	(<0.3)
SC-1	—	4.1	(5.4)
129/Sv MEF	—	3.6	(4.9)
RLE	—	<0.3	(0.6)
MLC	—	<0.3	(<0.3)
b		$\log_{10}$ ICPFU per plate	
EC	EC	<0.3	(<0.3)
EC	SC-1	3.1	(1.4)
EC	129/Sv MEF	2.6	(0.6)
EC	RLE	1.9	(<0.3)
EC	MLC	1.7	(<0.3)

*EC-A cells were supplied by Dr W. C. Speers as a subclone[25] of the PCC4azal embryonal carcinoma cell line derived from a teratocarcinoma of the 129/Sv mouse, as first described by Jakob et al.[19]. When grown as monolayers *in vitro* without feeder cells, less than 0.1% of these cells spontaneously differentiate without specific stimulation; PCC4azal and most other subclones spontaneously differentiate at higher frequencies. EC-A cells were grown in Eagle's minimal essential medium (EMEM) containing 10% fetal calf serum and antibiotics. The SC-1 murine cell line is highly permissive to type-C murine retrovirus infection[20]. 129/Sv MEF were secondary cells derived from 14-day embryos of a 129/Sv mouse. Rabbit lung epithelial (RLE) and mink lung cells (MLC)[21] are permissive for xenotropic and amphotropic viruses and non-permissive to ecotropic MuLV. M-MuLV is the exogenous Moloney strain of MuLV; the plaque-forming M-MuLV-148 subclone used in these studies has a ecotropic host range and grows well in mouse cells but very little, if at all, in cells from other species.

† Virus production was assayed by a quantitative infectious-centre XC plaque assay, SXC, that requires only a single cycle of infection in mouse cells[22]. Therefore, a single virus-producing mouse cell caused an XC syncytial-plaque expressed as an infectious-centre plaque forming unit (ICPFU). Cells were treated with DEAE dextran (25 μg ml⁻¹ for 30 min) before infection with M-MuLV at a multiplicity of 1–20 plaque forming units per cell. EC cells infected in this manner were allowed to adsorb virus for 1 h at 37 °C. The cells were then washed twice with EMEM and incubated for an additional 1–2 h to allow penetration of the cells by the adsorbed virus. The infected cells were lifted and washed extensively to ensure the elimination of any free M-MuLV that did not adsorb to the cells. These infected EC cells, as a single cell suspension, were plated on 35-mm diameter tissue culture plates at 2 × 10⁵ cells per plate, and an equal number of complementing cells was added. The cells were allowed to attach to the surface of the dishes for at least 2 h before fusion.

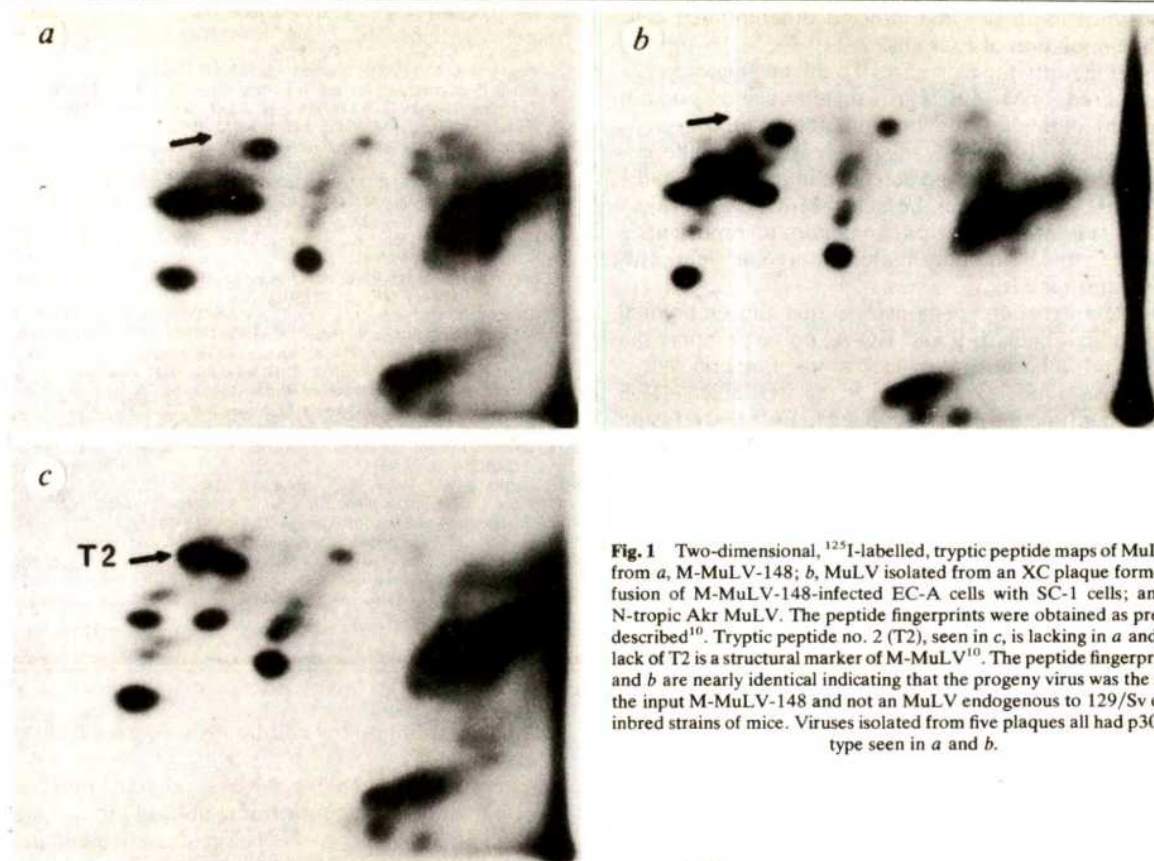
‡ Cells were fused with 47.5% polyethylene glycol (PEG) as described previously[23]. The efficiency of cell fusion and the toxicity of PEG to cells is difficult to estimate as these factors vary from one cell type to another and are highly dependent on PEG concentration, which can vary throughout an exposed plate due to the presence of residual media[23]. Cultures that were observed 3 h or more after PEG exposure had areas of non-viable cells, areas of large multinucleated heterokaryons, and areas of single cells and small heterokaryons. Viable cells (trypan blue exclusion) at 16 h after infection normally contained approximately 10% bi- and multinucleated heterokaryons. Multinucleated heterokaryons were lost from cultures that were carried for several generations. Similar results were obtained when cells were fused with inactivated Sendai virus, although there were fewer multinucleated heterokaryons formed and little if any toxicity. Fused or unfused infected cells were lifted 16 h after infection, before progeny virus-induced secondary infections could occur, counted, and dilutions of the single cell suspensions were cocultivated with XC cells and dexamethasone, as described[24]. Heterokaryons that produced progeny virus caused infection and fusion of surrounding XC cells resulting in syncytial plaques that were small relative to M-MuLV infected permissive mouse cells, suggesting that fewer progeny virus were produced by the fused cells.


Fig. 1 Two-dimensional, ^{125}I-labelled, tryptic peptide maps of MuLV p30s from *a*, M-MuLV-148; *b*, MuLV isolated from an XC plaque formed after fusion of M-MuLV-148-infected EC-A cells with SC-1 cells; and *c*, an N-tropic Akr MuLV. The peptide fingerprints were obtained as previously described[10]. Tryptic peptide no. 2 (T2), seen in *c*, is lacking in *a* and *b*. This lack of T2 is a structural marker of M-MuLV[10]. The peptide fingerprints of *a* and *b* are nearly identical indicating that the progeny virus was the same as the input M-MuLV-148 and not an MuLV endogenous to 129/Sv or other inbred strains of mice. Viruses isolated from five plaques all had p30s of the type seen in *a* and *b*.

possibility that plaques were caused by secondary infections of SC-1 cells by input M-MuLV liberated from EC cells after exposure to PEG.

Viruses were isolated from individual XC plaques and grown in SC-1 cells, after which peptide maps of the viral p30 core protein were obtained, as described previously[10]. Figure 1 shows that the p30 peptide maps contained markers specific for M-MuLV, indicating that the plaques were caused by progeny of the input M-MuLV, as opposed to a possible fusion-induced production of virus endogenous to the EC-A[11,12] or permissive cells. Therefore, heterokaryons formed between infected EC-A cells and uninfected permissive cells produced infectious progeny M-MuLV, whereas infected EC-A cells alone did not.

The efficiency of permissive cell complementation of M-MuLV growth in EC cells was dependent on the time of heterokaryon formation. M-MuLV-infected EC-A or F-9 cells were fused with uninfected SC-1 cells at various times after infection and assayed for infectious centres. As seen in Table 2, complementation of M-MuLV growth in EC cells was much more frequent when heterokaryons were formed 8–12 h after infection. Unexpectedly, before this time, and even after, fusion yielded little complementation of M-MuLV growth. These results suggest: (1) that the virus requires the host cell function only during a discrete period of its replication cycle, that is 8–12 h after infection; and (2) as heterokaryon formation before 8 h postinfection was not efficient in complementing M-MuLV growth, the host function must itself be labile and not replenished in the heterokaryon. Since the entire contents of the EC and permissive cells are present initially in heterokaryons, a dominant regulatory component of the EC cell apparently represses production of the required function that permissive cells express. This is not surprising when one considers the ability of EC cells to confer pluripotency to somatic cell hybrids between EC cells and thymocytes[13] or Friend erythroid cells[8] and suggests a generalized dominant nature of undifferentiated embryonic stem cells.

A separate, third, consideration is that complementation of M-MuLV production in infected EC-A and F-9 cells, by fusion

with uninfected SC-1 cells, decreases rapidly 12 h or more after infection (Table 2). After this interval, virus apparently cannot use the host component that complements M-MuLV growth in EC/permissive cell heterokaryons. This suggests that the virus has changed or is under different control after the period of complementation passes (8–12 h postinfection). We have isolated subclones of infected EC cells that are known to be non-productively infected with M-MuLV[14]. These cells cannot be induced to produce M-MuLV by fusion with permissive cells. This latter point is consistent with related studies with M-MuLV[7] and SV40[15], in which EC/permissive cell heterokaryons, formed several days after infection of EC cells, did not replicate virus, whereas fusion soon after polyoma virus infection did result in viral antigen expression[16]. Also, as complementation decreased when fusion occurred later than 12 h postinfection, it is unlikely that fusion simply allowed

Table 2 Temporal effect of SC-1 cell complementation of M-MuLV growth in EC-A and F-9 cells

			ICPFU per plate*					
		No	PEG fusion (h after infection)					
Expt	EC cell	PEG	4	8	12	16	20	24
1	EC-A	2	86	162	248	12	ND	0
2	EC-A	1	20	98	124	ND	3	ND
3	EC-A	0	0	14	40	12	ND	0
4	EC-A	8	70	860	787	86	12	ND
5	EC-A	26	112	690	1274	ND	118	ND
6	EC-A	1	30	110	114	ND	5	ND
6	F-9	0	37	180	228	ND	20	ND

*Subconfluent EC-A and F-9 monolayer cells were infected with M-MuLV, co-cultivated with SC-1 cells, fused with PEG, and assayed for XC plaque formation as described in Table 1. F-9 cells, a 'nullipotent' EC cell line that does not spontaneously differentiate in monolayer culture[26] were from Dr F. Dutko. F-9 cells were grown in monolayers on plastic tissue culture flasks or plates that had been previously treated with 0.1% gelatin at 4 °C for 2 h to enhance attachment. PEG fusion was timed from the first exposure of EC cells to M-MuLV. Numbers represent the average ICPFU for duplicate or triplicate plates at each time point. ND, Not determined.

amplification of virus in the few infected differentiated cells present in the population of EC cells.

These studies identify the existence of a missing factor in EC cells that is required for M-MuLV growth, although they do not specify the nature of the host function, possibly an enzyme(s) or organelle(s). Recent studies[17,18] suggest that the undifferentiated F-9 line of EC cells may be defective in producing stable SV40 RNA transcripts. Whether the lack of M-MuLV growth in F-9 and EC-A cells is a similar phenomenon, or represents a general characteristic of undifferentiated embryonic stem cells, has yet to be determined.

The data presented here demonstrate that the embryonal carcinoma stem cell lines, F-9 and EC-A, do not support the growth of M-MuLV because they lack a host function that is required for virus replication and must be available 8–12 h postinfection. This function can be supplied to EC cells by fusion with differentiated mouse, rabbit or mink cells. If this fusion-induced complementation of M-MuLV growth can be used to purify the responsible factor from permissive cells, the related function should become clear.

I thank W. C. Speers, R. M. Liskay, F. Dutko and R. A. Lerner for helpful criticisms.

Encephalomyocarditis virus infection of cultured murine pancreatic β-cells

G. L. Wilson, B. J. D'Andrea, S. C. Bellomo & J. E. Craighead

Department of Pathology, University of Vermont, College of Medicine, Burlington, Vermont 05405

Encephalomyocarditis virus (EMC) possesses many of the biological and pathogenetic features of the human Group B coxsackieviruses which have been implicated in the aetiology of insulin-dependent diabetes mellitus[1,2]. The M variant of EMC produces a diabetes-like disease when inoculated into some strains of mice. In these animals, cytolysis of β-cells is prominent, and there is an accompanying mononuclear inflammatory cell response (insulitis). Hyperglycaemia is observed during the acute stages of infection followed by varying degrees of carbohydrate intolerance[3–5]. In other mouse strains, β-cell lesions are less prominent and insulitis fails to occur, even though the animals develop a systemic infection. In these animals diabetes is observed either infrequently or not at all. Although the susceptibility of mice to the diabetogenic effect of the virus is believed to be influenced by one or more recessive genes, the pathogenetic basis for differences between the strains has not been defined[6,7]. The basis for the unique tropism of the M variant for β-cells also is uncertain because other serotypically similar strains of this virus cause pancreatic acinar cell necrosis, but lack a diabetogenic effect[3,5]. We have studied mouse pancreatic β-cells in tissue culture to determine whether or not these cells are uniquely susceptible to the M variant of EMC. Additionally, we examined the viral susceptibility of cultured β-cells derived from mouse strains that varied in their resistance to the diabetogenic effects of the M variant. The results show that cultured mouse β-cells can be infected by a variety of EMC viruses, and β-cells from different strains of mice are susceptible to infection by the M variant of EMC.

The majority of cells in our monolayer cultures stained positively by an immunoperoxidase technique[8,9] using anti-bovine insulin serum. The cultures secreted insulin into the medium at a gradually increasing rate for periods of longer than 1 month[10,11]. However, because the monolayers were prepared from fresh pancreata, the number of cells and the absolute amount of

insulin released into the culture dishes varied from experiment to experiment.

After maintenance for 9 days *in vitro*, monolayers were infected with 10^4 plaque-forming units of virus at an estimated multiplicity of infection of ~1. The deviation and properties of the M variant and the non-diabetogenic E (ref. 12), r^+ (ref. 13), and Mengo[14] strains have been reported[15]. The viruses were
Fig. 1 Monolayer cultures of mouse β-cells were prepared from the pancreatic tissue of 4- to 6-week-old mice. The isolated pancreata were dissociated in a phosphate-buffered saline solution containing 0.04% collagenase, 0.02% α-chymotrypsin, 0.03% DNase and 4% fetal calf serum. Rat β-cells were prepared by the method of Chick *et al.*[11]. β-Cell preparations were enriched using discontinuous Ficoll gradients and purified by differential adhesion and treatment with cysteine-free culture medium[24]. Cells were plated into multiwell plates (24 wells per plate, Co-Star) and maintained with Medium 199 (Gibco) containing 10% fetal calf serum, glucose (300 mg dl^{-1}) and gentamicin (1 mg dl^{-1}). The culture medium was replenished at 48-h intervals. Insulin in the culture medium was determined by the method of Wright *et al.*[25] using I^{125}-labelled porcine insulin (Cambridge Nuclear) diluted with cold porcine insulin (Dr Ronald Change, Eli Lilly), and guinea pig anti-bovine insulin serum (Linco) with purified mouse insulin (Novo) serving as a standard. Using this method insulin concentrations as low as 50 μU per ml of culture medium can be detected. Insulin release by β-cells in control cultures is displayed. The cultures were prepared from the pancreata of CD-1 and C57BL/6 mice and CD rats (Charles River). Data are expressed as a percentage of the insulin released during days 7 to 9 of culture. The 100% insulin concentrations averaged 1.5 ± 0.3 mU per culture for the CD-1 cultures, 0.5 ± 0.03 mU per culture for the C57BL/6 cultures and 10.6 ± 0.4 mU per culture for the CD rat cultures.

grown and titred in a continuous line of mouse fibroblasts (L-929) maintained in this laboratory.

Culture medium was collected at 48-h intervals after infection and assayed for insulin. Control cultures released insulin at a steady rate (Fig. 1). The results of insulin radioimmunoassays on the medium of infected β-cell cultures prepared from CD-1 mice are summarised in Fig. 2. Studies with the diabetogenic M and the non-diabetogenic E, r[+] and Mengo strains were conducted in a similar fashion. In replicate experiments insulin in the culture medium was reduced appreciably at 48 h after inoculation and was not detectable after 96 h. During this time cultures were monitored daily by phase contrast microscopy, and extensive cytolysis was observed. Thus, morphological evidence of cell death clearly supported the insulin data. The effects noted above were not influenced substantially by virus dosage. To exclude nonspecific cytotoxic effects of the viral inoculum and subtle changes in culture conditions, parallel studies were carried out with β-cell cultures prepared from neonatal rats. Insulin release by these cells was unchanged during the course of the experiments, and morphological alterations were not observed. Although it is possible that the procedure for the preparation of cultures altered mouse, but not rat, β-cells in such a way as to unmask hidden virus receptors, we feel this is unlikely. The 9-day culture period before infection should be of sufficient duration to permit repair of membrane components[16].

The results of experiments using β-cell cultures prepared from diabetes-prone CD-1 and resistant C57Bl/6 mice are shown in Fig. 3. Radioimmunoassays on the medium from these cultures demonstrated a comparable decline in insulin release, and similar cytopathology was observed.

It has been contended in other studies that genetic factors code for the presence of viral receptor density on the β-cell surface and thus determine susceptibility to the virus[17,18]. The morphological methods used by these investigators to identify β-cells are questionable, however, due to nonspecific staining[9,19]. If the cell cultures in their studies comprised a mixture of fibroblasts and pancreatic cells (acinar and insular), it seems likely that the assays could not assess definitively the receptor density of β-cells. Using insulin release as a measure of

Fig. 3 Insulin release by β-cells in culture after inoculation with EMC M variant virus. The cultures were prepared from the pancreata of CD rats, CD-1 mice and C57BL/6 mice. Data are expressed as a percentage of the insulin released in each culture during the 48-h period immediately preceding inoculation (mean ± s.e.m. of four observations). The average 100% pre-inoculation insulin concentrations are: 10.2 ± 0.3 mU per culture (CD rat); 1.5 ± 0.1 mU per culture (CD-1 mouse); and 0.5 ± 0.02 mU per culture (C57BL/6 mouse).

viral induced cell injury, we found no difference between β-cells from mice resistant and susceptible to the diabetogenic effect of the virus. Moreover, several antigenically similar, but non-diabetogenic, EMC virus strains infected β-cells in culture. Thus, β-cells *in vitro* fail to exhibit unique susceptibility for the M variant.

Recent *in vivo* studies in our laboratory indicate that the islets of resistant mice sustain significant cytological injury. Although pancreata are depleted of insulin during the acute stages of infection, hyperglycaemia fails to develop. We have also found that alterations in the metabolic state of mice affect the severity of β-cell damage and the expression of diabetes (refs 20, 21 and B.J.D'A., G.L.W. and J.E.C., unpublished data). Similarly, culture conditions could affect susceptibility of β-cells to this virus[22,23]. Our observations do not exclude the possibility that viral susceptibility of β-cells in the intact animal is a consequence of the presence of specific receptors. We suggest, however, that other factors such as metabolic influences also are critical determinants affecting viral susceptibility and injury to β-cells.

Fig. 2 Insulin release by β-cells in culture after inoculation with various strains of EMC virus. The cultures were prepared from the pancreata of CD rats and CD-1 mice. Data are expressed as a percentage of the insulin released in each culture during the 48-h period immediately preceding inoculation (mean ± s.e.m. of four observations). The average 100% pre-inoculation insulin concentrations for the CD rat and CD-1 mouse cultures, respectively, are: 8.6 ± 0.6 mU per culture and 1.5 ± 0.1 mU per culture (E variant); 10.2 ± 0.3 mU per culture and 1.5 ± 0.1 mU per culture (M variant); 9.5 ± 0.3 mU per culture and 1.3 ± 0.07 mU per culture (Mengo); and 7.9 ± 1.5 mU per culture and 1.4 ± 0.03 mU per culture (r[+]).

Non-mendelian mutation affecting ribulose-1, 5-bisphosphate carboxylase structure and activity

R. J. Spreitzer & L. J. Mets

Department of Biology, Case Western Reserve University, Cleveland, Ohio 44106

Chlamydomonas reinhardii, **a haploid unicellular green alga, is the only organism in which the non-mendelian (uniparental) genes thought to reside in chloroplast DNA have been observed to recombine. Thus, genetic mapping by recombination analysis is possible, and a single linkage group with a large number of markers has been characterized[1,2]. Although circumstantial evidence is consistent with the hypothesis that this uniparental linkage group is located in the chloroplast,[1,2] there is no direct evidence associating any of the known markers with chloroplast DNA. As the gene for the large subunit (LS) of ribulose-1, 5-bisphosphate carboxylase (RubPCase) has been located on the physical map of *C. reinhardii* chloroplast DNA,[3,4] a genetic marker in this same gene would help to prove the relationship between the uniparental linkage group and chloroplast DNA. We have now succeeded in isolating a mutation in a *C. reinhardii* gene which controls the structure and function of the LS of RubPCase. This new genetic marker will serve as the first reference point in our efforts to correlate the physical and genetic maps for the chloroplast genome. At the same time, the fact that we have obtained this mutant should encourage further attempts to produce genetic modifications of this key photosynthetic enzyme with the goal of improving plant productivity[5].**

RubPCase is an oligomeric enzyme which has two important enzymatic activities. The holoenzyme has eight copies of the 55,000 molecular weight MW LS and eight copies of a 12–20,000 MW small subunit (SS) which is a nuclear gene product[6]. Net CO_2 fixation during photosynthesis depends on the RubPCase-catalysed carboxylation of ribulose-1, 5-bisphosphate in the Calvin cycle[7]. On the other hand, the enzyme also catalyses the reaction of O_2 with the same substrate. This reaction, which is the first step in photorespiration, leads ultimately to CO_2 evolution and an apparently wasteful consumption of Calvin cycle intermediates which might otherwise be used for CO_2 fixation[7]. The catalytic site, which seems to be the same for both the carboxylase and oxygenase activities[8], is located on the LS [7].

Non-photosynthetic mutants of *C. reinhardii*, including presumptive LS mutants, can be maintained on medium containing acetate. Many such mendelian [9] and also uniparental [10] acetate-requiring mutants have been isolated, but only one has been found with a specific defect in a Calvin cycle enzyme (phosphoribulokinase) [11]. We reasoned that a Calvin cycle mutant, in addition to having an acetate-requiring phenotype, might be photosensitive as a result of the build-up of unused reductant generated by an active photosynthetic electron transport system. A light-sensitive phenotype would also account for the apparent rarity of RubPCase mutants, and Calvin cycle mutants in general, because selection experiments have usually been carried out at high light intensities. Taking this into account, we adopted a mutant selection protocol which would allow the recovery of light-sensitive, acetate-requiring mutants.

Independent cultures of wild-type *C. reinhardii*, strain 2137 mt[+] (ref. 12), were grown in 10 mM sodium acetate medium in the dark at 25°C until they reached stationary phase. To enhance uniparental mutant recovery, 1 mM 5-fluorodeoxyuridine was included in these cultures[13]. Cells were then collected, washed by centrifugation and mutagenised with ethyl methanesulphonate[14]. Washed cells were grown in the dark in acetate medium to allow expression of mutant phenotypes. Cells from each of these cultures were plated at 100–500

cells per plate onto acetate medium in the dark. Colonies were replica plated to medium without acetate and placed in 4,000 lx cool white fluorescent light. Colonies unable to grow on this minimal medium were recovered at a frequency of one per 10^3 cells plated, and included both mendelian and uniparental acetate requirers, as determined by standard tetrad analysis[15]. All the uniparental mutants were light sensitive, growing better in the dark with acetate than in the light (2,000 lx) with acetate.

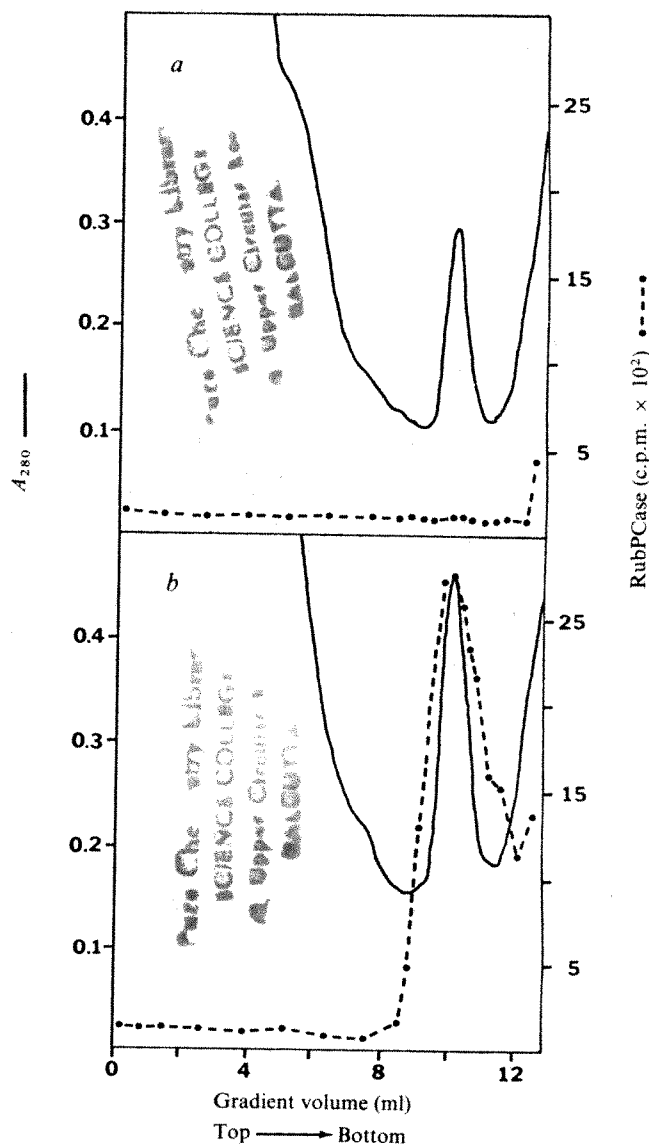
RubPCase was purified from all the uniparental mutants by sucrose gradient centrifugation[16] and subjected to isoelectric focusing (IEF) in 8 M urea[17]. Molecular weights were determined by two-dimensional SDS-polyacrylamide gel electrophoresis[17] and used to verify the identity of the RubCase LS and SS bands observed on the first-dimension IEF gels[12,18].


Fig. 1 Sucrose gradient centrifugation and assay of RubPCase from *rcl-u-1* and wild type. *a*, *rcl-u*1-10-6C; *b*, wild type. Cultures were grown in acetate medium in the dark. Approximately 6×10^8 cells were sonicated at 0 °C in 1.5 ml of sonication buffer: 1 mM dithiothreitol (DTT), 5 mM $MgCl_2$, 10 mM $NaHCO_3$ and 50 mM Tris base, *p*H 7.5. Following centrifugation at 27,000*g* for 15 min, 1 ml of the supernatant was layered onto a 12-ml linear sucrose gradient (10–30% sucrose in sonication buffer), which was run in an SW-40 rotor at 37,000 r.p.m. for 20 h at 4 °C. The gradient was fractionated into 0.3-ml fractions and scanned at 280 nm. RubPCase was assayed[16] by mixing 0.1 ml of a sucrose gradient fraction with 0.1 ml of reaction mix: 1 mM DTT, 15 mM $MgCl_2$, and 90 mM NaH $^{14}CO_3$ (0.22 μCi μmol[-1]). After 15 min at 25 °C, the reaction was terminated with the addition of concentrated HCl/acetic acid (4:1) and the samples were then processed for liquid scintillation counting.

Fig. 2 IEF of RubPCase from reciprocal crosses between rcl-u-1 and wild type. *a*, rcl-u-1 mt⁺X wild-type mt⁻: (1) rcl-u-1 mt⁺; (2) wild-type mt⁺; (3) mixture of (1) and (2); (4)–(7) progeny from a single tetrad. *b*, Wild-type mt⁺ X rcl-u-1 mt⁻: (1) wild type mt⁺; (2) rcl-u-1 mt⁻; (3) mixture of (1) and (2); (4)–(7) progeny from a tetrad. Mendelian markers present in the crosses segregated 2:2 among the progeny. The SS on gels B5 and B7 did not reproduce well in the photograph. All parents and progeny were grown in acetate medium in the dark. RubPCase was purified by sucrose gradient centrifugation (Fig. 1). Samples obtained from the gradient were prepared by adding solid urea to 9M, and applied to 13.5×0.4 cm gels as 50-μl aliquots (5–50 μg RubPCase). IEF was carried out[17] with pH 5—7 ampholines and 8M urea in polyacrylamide gels for 12 h at 400 V and 1 h at 800 V constant voltage at 25 °C. The gels were stained in bromphenol blue and Coomassie blue. The pH gradient was measured with stab pH and reference electrodes on fresh gels. This showed that the isoelectric point of the SS was 7.4 and that of the wild type LS was 6.3.
One mutant was found to have a lower isoelectric point for the LS. This mutant, named rcl-u-1-10-6C (rcl-u-1 referring to its genetic locus), was a stringent acetate requirer that could not be maintained on acetate medium above 2,000 lx, but grew as well as wild type in the dark. Although rcl-u-1-10-6C maintained normal levels of RubPCase holoenzyme (Table 1), RubPCase activity was absent (Fig. 1). Further biochemical analysis (Table 1) showed that the mutant had normal levels of photosystem II (PSII) activity and chlorophylls, but lacked the ability to fix CO_2. The mutant was indistinguishable from wild type in holoenzyme sedimentation value (Fig. 1) and in LS and SS MW (data not shown). Reciprocal crosses indicated that the altered LS was inherited in a uniparental pattern (Fig. 2), along with the light-sensitive, acetate-requiring phenotype.

The evidence presented suggests that rcl-u-1-10-6C is a mutation in the chloroplast structural gene of the LS. Unlike other presumptive RubPCase mutants[19,20], the mutant phenotype is inherited in a uniparental pattern, which is the pattern expected for a mutation in a chloroplast gene[21,22]. Because the mutant maintains normal PSII activity, amount of chlorophyll, and amount of RubPCase protein, defects in chloroplast protein synthesis or other defects which exert pleiotropic effects can be

ruled out. This is not the case for several maternally inherited mutants of *Oenothera* which have been presumed to be LS structural gene mutants[23]. In contrast to other presumptive RubPCase mutants[19,20,23,24] rcl-u-1-10-6C is the first mutant in which a change in LS structure is evident. Because apparently normal holoenzyme structure exists in the mutant, major processing errors are probably not responsible for the LS alteration. The difference in IEF properties between the mutant and wild-type LS could be due to a difference in primary amino acid sequences, or a difference in secondary modification. The critical discrimination between these two possibilities requires comparative sequence analysis of the two proteins. In either case, rcl-u-1 is a uniparental gene which controls the apparent charge and activity of the RubPCase LS. We are now determining whether this gene is linked to the other uniparental genes in *C. reinhardii*.

The photosensitivity of rcl-u-1-10-6C must be considered in designing protocols for obtaining additional mutants. Light intensities in excess of 2,000 lx, as have been used by other workers[10], would not allow this mutant to survive. We have not investigated the mechanism of photosensitivity in this mutant, but we know that light-sensitive phenotypes are not confined to mutants with Calvin cycle defects. We have recovered many light-sensitive, non-photosynthetic mutants with specific defects either in PSI or in PSII. Each group includes both mendelian and uniparental mutants, which will be discussed in detail elsewhere.

This work was supported by a grant from the NSF.

Table 1 Biochemical comparison of rcl-u-1-10-6C and wild type

	rcl-u-1-10-6C	Wild type
CO₂ fixation (μmol per h per mg Chl)	12	640
PSII activity (DCPIP) (μmol per h per mg Chl)	135	144
Chlorophyll $a + b$(Chl) (mg per 1×10^9 cells)	1.11	1.30
RubPCase protein (mg per 1×10^{10} cells)	4.39	4.36

Cultures were grown in acetate medium in the dark. CO_2 fixation was assayed by adding 0.2 ml of 50 mM NaH $^{14}CO_3$ (0.5μCi μmol^{-1}) to 2×10^7 cells in 2 ml of minimal medium at 25 °C and 60,000 lx (ref. 12). For PSII activity, cells were sonicated at 4 °C in reaction buffer: 2.5 mM $MgCl_2$, 20 mM KCl, 1 mM K phosphate buffer (pH 7.0)[25]. The lysate was centrifuged at 480g for 5 min and the supernatant was diluted 10× with 0.1 mM dichlorophenol indophenol (DCPIP) in reaction buffer. The red light-dependent (180 μE m^{-2} s^{-1} between 640 and 740 nm) reduction of DCPIP was measured spectrophotometrically at 25 °C. Chlorophyll (Chl) was measured spectrophotometrically in 80% acetone extracts of whole cells[26]. RubPCase protein was estimated from the absorbance at 280 nm of the RubPCase peak on sucrose gradients[16].

MATTERS ARISING

A 'random transition' in the cell cycle?

EVIDENCE is presented by Shields[1], partly mathematical and partly from real and simulated experiments, that the cell cycle contains an exponentially distributed phase. Unfortunately, there are flaws in his probabilistic argument at two points. His conclusions are probably not invalidated, but it seems appropriate to point out the errors in the hope that they will not be repeated elsewhere.

We are concerned with the probability distribution of cell cycle times, and with the distribution of the difference in cycle time of sister cells. It seems that sister cycle times T_1, T_2, say, may be well represented in terms of three independent random variables T_B, U_1, U_2 as

$$T_1 = T_B + U_1$$
$$T_2 = T_B + U_2 \qquad (1)$$

Here, U_1 and U_2 are identically distributed, whereas T_B is common to the two sisters and must be a non-constant random variable for T_1 and T_2 to be correlated. Shields himself mentions that the T_i values are correlated, quoting a typical value for the correlation coefficient of 0.78; according to representation (1) above, the correlation is in general

$$\rho(T_1, T_2) = \frac{\mathrm{Var}(T_B)}{\mathrm{Var}(T_B) + \mathrm{Var}(U_i)} \qquad (2)$$

In contradiction to this, Shields then assumes that T_1 and T_2 are independent, in order to derive an expression for $\beta(t)$, the survivor function of $|T_1 - T_2|$, in terms of $Q(t)$, that of T_i. In fact, this argument may be rescued: in view of representation (1), $|T_1 - T_2| = |U_1 - U_2|$. On the basis of empirical α curves, we might assume the model

$$Q^*(t) = Pr\{T_i > t + T_B\}$$
$$= Pr\{U_i > t\}$$
$$= \exp(-kt), \qquad t \geqslant 0, i = 1, 2 \qquad (3)$$

from which it is true that

$$\beta(t) = Pr\{|T_1 - T_2| > t\}$$
$$= Pr\{|U_1 - U_2| > t\}$$
$$= \exp(-kt), \qquad t \geqslant 0 \qquad (4)$$

This approach is tantamount to redefining Shields' function $Q(t)$ as a conditional survivor function.

The second flaw concerns Shields' claim at the end of paragraph 5 that representation (4) implies representation (3). This
Fig. 1 Semi-logarithmic plot of $Q^*(t) = \left(1 + 2d^2 \sin^2\left(\frac{kt}{d}\right)\right) e^{-kt}$ against t for $k = \frac{1}{8}$ and $d^2 = 0, \frac{1}{8}, \frac{1}{4}, \frac{3}{8}$ and $\frac{1}{2}$.

is not the case, and many other forms of $Q^*(t)$ give the same expression for $\beta(t)$: for example, the whole family

$$Q^*(t) = \left(1 + 2d^2 \sin^2\left(\frac{kt}{d}\right)\right) \times$$
$$\times \exp(-kt), \qquad t \geqslant 0 \qquad (5)$$

as d varies from 0 (corresponding to representation (3)) to $1/2^{1/2}$. These solutions are illustrated in Fig. 1; presumably, however, they are rather unlikely to represent correctly the biological reality. Further, Shields' observation that exponential β curves are obtainable irrespective of the age of the younger of a sister pair is, of course, conclusive evidence that representation (3) is the correct solution, as such curves completely determine the joint distribution of (T_1, T_2).

I thank Russell Smith for finding the counter-example (5) above.

PETER J. GREEN

Department of Mathematics,
Science Laboratories,
South Road,
Durham DH1 3LE, UK

1. Shields, R. *Nature* **273**, 755–758 (1978).

SHIELDS REPLIES—Green is quite right to point out that the cell cycle times of sister cells are frequently correlated and that my equation for the distribution of differences of sister cell cycle times is not valid without qualification. We have argued that correlations in the cycle times of sister cells arise because the cell cycle consists of two parts, one of which (the B phase) is common to the sisters, whereas the other (A state) is independently and identically distributed. According to this model, the correlation of cell cycle times of sister cells arises from the identity of the B phase, the differences from the A state. If these assumptions are correct, what does an exponential distribution of differences in cell cycle time (the β curve) tell us? Green points out that many A state distributions will give exponential curves (an example is given in his paper); this is why I added the condition that exponential β curves were obtained irrespective of the cell cycle times of the younger cell in the cell pair when curves are calculated from cohorted data.

If this condition is met, then, as Green pointed out, the A state must be exponentially distributed. However, if A states are not independently and identically distributed, other cell cycle models can be devised which give exponential β curves (D. Rigney, personal communication). What I had intended to do was to focus attention on the statistic $|T_1 - T_2|$, which has been largely ignored in cell cycle analysis. It should not be forgotten that any proposed cell cycle model should explain the exponential nature of $|T_1 - T_2|$ as well as give a description of the overall distribution of cell cycle times in a cell population. A modified version of the original transition probability hypothesis seems to do this successfully[1].

BOOK REVIEWS

The road to equality

Eric Ashby

THE fear that Western civilization will collapse from exhaustion of resources was the Great Red Herring of the 1970s, deflecting our attention from a more likely cause of collapse: the unequal distribution of resources. In the 1980s we shall, I hope, get back to the problems that really matter, namely how to persuade — and, if we fail to persuade, compel — affluent nations to share their resources of food, stored energy and mineral wealth, with nations that lack one or other of these resources. If America and Canada cut down their acreage of grain crops, if the Arabs decide to keep their oil in the ground, if South Africa and Zimbabwe stop the export of chromium, the prime danger will not be privation; it will be war. The way ahead, in the short term at any rate, is now becoming clearer. It is not to pursue the mirage of zero growth, nor is it to let the market economy rip in a frenzy of free competition; it is to continue growth with prudence, cutting down waste, protecting the environment, and to distribute the products of growth with greater equity than nations have ever shown in the past.

This is the theme in what (to my mind) is the most important statement about the human condition that has been made in the last decade: the book of essays entitled *World Futures* produced from the Science Policy Research Unit in the University of Sussex (reviewed in *Nature* **276**, 144-146; 1978). *World Futures* is a symposium by several authors. It does not ram a message down the reader's throat; it offers him the facts and leads him (with skilful encouragement by Marie Jahoda in the concluding chapter) to a choice among four options: high growth, high equality (a big cake fairly shared); high growth, low equality (a big cake hogged by the rich); low growth, high equality (a small cake fairly shared); and low growth, low equality (a small cake hogged by the rich). Marie Jahoda's choice is for the big cake fairly shared.

John Gribbin has written an epitome of *World Futures*. It is about half the length of the original book. One reason he gives for having written it is that *World Futures*

Future Worlds. By John Gribbin. Pp.225. (Sphere:London, 1979.) Paperback £1.75.

---

is "inevitably intimidating to the more casual reader". I'm afraid I don't like this reason. There are some issues — and this surely is one of them — on which people can't afford to be casual. If they will not take the trouble to read 390 pages of closely argued, but non-technical essays about the future, they have no right to hold opinions about the future.

But there are other reasons, and good ones, why John Gribbin wrote this book. First, he was associated with the team — though not a member of it — so his book is not just a rehash of *World Futures* with the title reversed: it is an observer's reflections on the work at Sussex. Second, he is an experienced journalist, skilled in the art of turning casual readers into serious readers. Third, he has picked out the preferred option — a big cake fairly shared — and concentrated on that, adding opinions of his own. So although the book is an epitome of *World Futures* it is a judiciously selected epitome.

If you put your faith in the possibilities of a high-growth, high-equality option, you have to be persuaded that the potential for high growth is present. Gribbin believes that it is, in the short term at any rate; and in this view he is supported by the recently published report sponsored by OECD, known as *Interfutures* and summarized in the *OECD Observer* last September. Enough food is already grown in the world to provide the estimated world population with a diet of over 2,000 kilocalories a day, if only the food was "available in the right place, at the right time, at a price they can afford". Millions of people live at starvation-level because they can't buy food, not because there is no food to buy. For energy the position is more complicated and more dangerous. Gribbin makes the point that reserves of recoverable coal are very large and that the really ominous problem is to ensure supplies of energy in the forms we need.

With a rigorous insistence on economies, the demand for electrical energy may reach a peak; for it can't be efficiently stored and already a power station has to be built to cope with peak loads, leaving the station (a slight exaggeration, perhaps) "twiddling its thumbs while waiting for a frosty day". An all-electric world is not a likely scenario for the future. So Gribbin gives the (now) conventional answer: we must plan for a mix of energy sources, anticipating the exhaustion of natural gas, which in 1974 provided some 21% of the Western world's supplies of energy; and the perpetual threat of a strangulation in oil supplies, which in 1974 provided 45% of the energy; and a return to coal (the proportion of which, in the energy balance sheet, dropped from 90% in 1900 to 32% in 1974), supplemented by nuclear energy and energy from sun, wind and vegetable products. Over the third prerequisite for high growth — raw materials — Gribbin is optimistic, indeed more so than is justified by such data as we have. It is true that aluminium replaces copper for some purposes, and glass fibres may replace some metals; but there are awkward problems about finding substitutes for some raw materials, mercury and lead, for example. It is here that 'use less' is likely to be the only practicable policy.

Gribbin's conclusion from this analysis is that the high-growth option, in the short term, is a practicable option. What about the other term in the equation: more equality? Here Gribbin, and indeed all analysts of the future, are obliged to speculate in the murky waters of political science. Put crudely, and in a vastly simplified form, the position is as follows. Without a massive transfer of material wealth from North to South, from 'haves' to 'have nots', there will be (1) insufficient markets for the 'haves' to establish high growth, and (2) mounting geopolitical tensions leading to conflict. But, in order to make a massive transfer of material wealth from North to South, the 'haves' in the North will have to make sacrifices. How is a nation persuaded to make sacrifices? Only (if history is any guide) for

fear of something worse than the sacrifices they are asked to make. Under a threat from outside, as in time of war, people will endure severe privation. But when the threat is from within, caused by strains upon the economic and social system, we just do not know what privations people will be prepared to accept. The danger is that we shall find ourselves on the brink of internecine conflict before we realize that problems about the equitable distribution of food and energy are — as President Carter has fruitlessly reminded the American people — "the moral equivalent of war".

An outstanding feature of *World Futures* is a discussion of the four options, ranging from 'big-cake-fairly-shared' to 'small-cake-hogged-by-the-rich', as regarded by people of different political persuasions: conservatives, reformists and radicals. Gribbin gives a good summary of the interaction of these three political attitudes toward his preferred option. He sets out what it might be like to live in a high-growth, high-equality world under

one or other of these three styles of government. The radicals would reach this kind of world through revolution and a phase of dictatorship. Conservatives would see it evolving naturally as more and more people find satisfaction in the share of the cake they get. Reformists would hope to make the transition by a technocratic managed economy which somehow (but how?) would preserve the traditional freedoms of Western democracy. Under all styles of government there would be an alarming increase of unemployment which would euphemistically be called leisure. And this is the sixty-four dollar question for all studies about the future: how to replace the work-ethic of the nineteenth century by a leisure-ethic for the twenty-first century. One of the essays in *World Futures* does ask the question. No one yet has provided a credible answer. ☐

Catalysis at work

V. Gold

Enzymic and Non-Enzymic Catalysis. Edited by P. Dunnill, A. Wiseman and N. Blakebrough. Pp.250. (Ellis Horwood: Chichester, UK. Distributed by Wiley: Chichester, UK, and New York, 1979.) £19.75, $50.

IN April 1978 the Microbiology, Fermentation and Enzyme Technology Group of the Society of Chemical Industry initiated an international gathering of biochemists, chemists and chemical engineers. The purpose of the meeting was a discussion of topics of common interest in the general field of catalysis by enzymes and enzyme-like materials, especially the status and industrial potential of stereoselective catalysis. The volume under review contains a full account of the proceedings, including a verbatim record of about 20 pages of more or less ephemeral discussion remarks. Its nine chapters can be clearly divided into two groups. The first group is devoted to biochemical and chemical studies, and the second to the design and performance of catalytic reactors. One hopes that the meeting produced much mutual education of and by the two groups of participants. The industrial exploitation of the remarkable effects of enzymes and the simulation of enzyme-like catalysis by synthetic materials represent tremendous challenges of potential industrial importance. This message is rather well conveyed by the volume. Of course, things have not stood still in the period since the meeting, and fuller or more up-to-date reviews of some of the topics are available elsewhere. The publication of the book will nevertheless have been justified if it succeeds in creating a greater appreciation, in universities and industry, of the promising possibilities in this area of endeavour.

The scope of the book is by no means comprehensive, and its content is fairly well reflected by the following, sometimes paraphrased, chapter headings: present knowledge of enzyme catalysis (A.R. Fersht, 12 pages); current status of enzyme technology (P. Dunnill, 22 pages); enzymes in organic synthesis (J.B. Jones, 27 pages); enzyme analogues, mostly of the crown ether type (J.F. Stoddart, 25 pages); micellar catalysis (J.M. Brown *et al.*, 17 pages); performance of non-biological catalyst reactors (R.E. Goddard, 42 pages), and of enzymic reactors (J.-M. Engasser, 26 pages); asymmetric homogeneous catalysis (D.J. Thompson, 17 pages); polymer-attached homogeneous catalysis (R.H. Grubbs and S.-C. H. Su, 12 pages). Most of the chapters in this very attractively produced volume include informative lists of references. ☐

V. Gold is Professor of Chemistry at King's College, University of London, UK.

Advice on techniques in IR spectroscopy

M.A. Ford

Applied Infrared Spectroscopy. By A. Lee Smith. Pp.336. (Wiley: New York and Chichester, UK, 1979.) $38.30, £17.40.

THE concept of this book can best be described by using the author's own words: "It is a volume based on practical experience, stressing the fundamental concepts and limitations of analytical IR spectroscopy for the chemist". Reference to "the chemist" is important, as a reasonable knowledge of chemistry is assumed. And the "practical experience" is very apparent, as there is wealth of advice on good spectroscopic techniques and the avoidance of pitfalls.

The main chapters cover instrumentation, sampling techniques, qualitative applications and quantitative applications with — rightly — by far the greatest emphasis on qualitative aspects. There is also a short chapter entitled "Spectroscopic Literature" concerned with collections of reference spectra and retrieval systems.

Instrumentation is described very adequately without going into excessive detail and the chapter includes descriptions of all the less common types of spectrometer, for example, Hadamard transform, as well as 'conventional' ones. Very useful advice is given on "optimising the spectrometer variables" and "performance tests and spectrometer calibration". There are two small points on

which I would take issue with the author; blazing a grating increases the intensity at a certain angle of incidence rather than "in a certain order", and noise and signal: noise ratio are more conventionally spoken of in terms of a notional peak to peak noise rather than the RMS value.

In the chapter on sampling techniques, the extent of the author's practical experience is very obvious and even a well experienced spectroscopist is likely to pick up some useful tips. Some techniques are, of necessity, covered only briefly but the reader is always referred to the relevant publications in the excellent bibliography.

A large part of the chapter on qualitative applications is devoted to a good general introduction to the theory of IR absorptions and the concept and use of group frequencies. Interpretation of spectra is covered relatively briefly but, again, there are full references to the available literature and there is much good advice. In addition, extensive correlation charts and lists of characteristic group frequencies are given in appendices. There is also a short description of typical applications.

The final chapter on quantitative applications emphasizes the need for good experimental technique — and very good advice is given — and the need to know "how precise the determination must be". There is good coverage of all commonly, and most less-commonly, used methods and again a full bibliography is given.

Overall, this is an excellent book which can be strongly recommended to both new and experienced IR spectroscopists. ☐

M.A. Ford is Technical Director of Perkin-Elmer Limited, Beaconsfield, UK.

Comparative decomposition

P.W. Flanagan

Decomposition in Terrestrial Ecosystems.
By M. Swift, O. Heal and J. Anderson.
Pp.400. (Blackwell: Oxford, 1979.)
£22.50.

IN AN ecosystem sense, decomposition simply means the disassociation of the constituent elements of organic matter with concomitant release of energy and increase in entropy. This volume is a documented synthesis of the study of decomposition in varying organic residues across different terrestrial ecosystems. It goes to a crucial additional step by attempting to relate decomposition processes to the functioning of the entire ecosystem and succeeds more than any other volume presently available. It is both specific in detail and comprehensive in scope.

The first two chapters review ecosystem-level perspectives on decomposition processes so that they may serve as the basis for an analysis in depth of the decomposer organisms and their activities (Chapter 3). In Chapters 4, 5 and 6, respectively, the influences of substrate quality, soil chemistry and climate on decomposition are examined and compared within and between ecosystems. The last chapter returns the reader again to the wider view and correlates all the fundamental biological, climatic and chemical factors to show how they operate together to produce

the process of decomposition to varied degrees in latitudinally separated ecosystems.

It is an extremely well documented account of the perspectives and accomplishments of those scientists working within and alongside the International Biological Programmes' committees of 'Dirty Rotters', i.e. the microbiology and decomposition working groups. In large part, it pre-empts the necessity for an interbiome synthesis of decomposition data and is consistent with the modern principles of microbial ecologists, soil biologists and students of decomposition in ecosystems.

The authors are to be complimented for explicating the reservations felt by many concerning the use of the *K* constant in studies of decomposition.

In a book of this scope there are sure to be aspects where coverage is insufficient to satisfy individual readers. I would like to have seen more emphasis given to the measurement of microbial and microfaunal biomass and to the tentative estimates of turnover in microbial subsystems. Other reservations about this volume include the fact that there was insufficient reference to work done in the Southern Hemisphere, New Zealand, Australia and South America, and proportionally too much to that done in the Northern Hemisphere, particularly to data from North America.

Figure 7.4 on p.279 caused me concern when it first appeared in another volume. It implies that in order for decomposition processes to increase in rate, the rate of primary productivity must decline. This inference could be very misleading.

Sometimes the generalizations are too broad — for example, referring to the taiga forest ecosystem: "Water is in excess all year around . . .". This is certainly not the case. Most decomposition processes in organic layers of taiga forests suffer from water deficiency throughout the summer season. Also, in tundra biological activity goes on throughout the year, though microbial processes do cease for 5–7 months.

Still, these are small imperfections in an otherwise first-rate volume. I feel that this book will become the standard reference text for students of decomposition in the 1980s. It is one of the most exciting books produced in this field since 1881 and Charles Darwin's *The Formation of Vegetable Mould through the Action of Worms with Observations on their Habitats* . . . . I am sure it will provide stimulus for students of microbial ecology, decomposition, agriculture, forestry and general ecology, as well as for anyone who just wants to know more about vital processes in natural environments.

The names of the authors guaranteed that the treatment exhibited substantial hybrid vigour. Meshing the intuition and experience of field-seasoned mycologists, soil zoologists and the experience of interbiome (IBP) synthesis has resulted in an excellent book for teaching and research reference in microbial ecology and decomposition. □

P.W. Flanagan is Professor of Microbiology at the Institute of Arctic Biology, University of Alaska, Fairbanks, Alaska, and represented the US (IBP) Tundra Biome on International Decomposition and Microbiology Working Committees.

Seeing the wood for the phylogenetic trees

Barry Cox

Phylogenetic Analysis and Paleontology.
Edited by Joel Cracraft and Niles Eldredge. Pp.233. (Columbia University Press: New York and Guildford, UK, 1979.) Hardback $28.10; paperback $11.25.

IT is unlikely that, in the days following his vision on the road to Damascus, St Paul was widely famed for the variety of his after-dinner conversations, or that Moses found it easy to say anything nice about the Golden Calf. Missionaries, and especially the recently converted, tend to be obsessional, and also simplistic in their wholesale condemnations of the "old ways". Similarly, the advent of what is now commonly called "cladistic systematics" was accompanied by a

polarization of many systematists into one of two camps — cladists or traditionalists. The errors of any partisan, once identified, were then hailed as the inevitable faults of his whole ideology, and used as sticks to belabour all his supporters. The voice of reasoned debate all too quickly rose to the shrill shriek of the pedlar of magic potions. Not surprisingly, many systematists invoked a curse on both their houses, and went about their business until the dust had settled, and better tempers had returned. It looks as though that time has arrived.

This volume is based on a symposium on "Phylogenetic Models" which took place during the North American Paleontological Convention in 1977, and contains seven essays debating the values of the cladistic and of the traditional methods.

There are four papers by supporters of cladistic methods. The first, introductory, paper is by Cracraft, who points out the similarity between cladistic systematics (in which no taxon is ever considered as ancestral to another) and the model of speciation by punctuated equilibria (in

which it is predicted that ancestors will rarely be identifiable, because a new species arises by rapid change in a peripheral, isolated population). Gaffney and Eldredge give accounts of the methods of the cladistic approach, with examples from their own fields of work. Here I preferred Eldredge's clear distinction between cladograms (showing the pattern of character-distribution), phylogenetic trees (showing the hypothesized relationships of the taxa) and "scenarios" (in which an attempt is made to explain the reasons for what appears to have taken place). Though asked to write a pro-cladist commentary on the symposium as a whole, Wiley instead devotes most of his space to an account of what he calls the "evolutionary species concept".

Appearing for the traditionalists are Gingerich and Bretsky, who argue that species have a considerable range in time and space, and that the range of variation within a species is also so wide that a method which totally rejects any possibility that an ancestor–descendant relationship can be recognized is unnecessarily narrow.

Bretsky also points out that the vicariance model of speciation implies that much speciation will be gradualist within one of the newly separated areas, so that preservation of ancestor–descendant lineages may not be so rare, and that the palaeontological record may in some cases be far more complete than is generally thought. In his commentary on the symposium on behalf of the traditionalists,

Boucot acknowledges that the cladists have made an important contribution to systematic taxonomic procedures in insisting on methodically constructed diagnoses; he also gives useful critiques of the other contributions.

There is inevitably some overlap in the various pro-cladistic expositions of the methods and merits of the technique of phylogenetic analysis by the evaluation of

the patterns of distribution of novel characters amongst the taxa. But the papers are on the whole stimulatingly written, with useful examples of the use of the different methods, and with a more balanced, less chauvinist attitude to the views of the opposition than had previously been common. □

Barry Cox is Professor of Zoology at King's College, University of London, UK.

Problems in carbon-13 NMR

Elizabeth A. Williams

Carbon-13 NMR Based Organic Spectral Problems. By Philip L. Fuchs and Charles B. Bunnell. Pp.316. (Wiley: New York and Chichester, UK, 1979.) Paperback $14.97, £7.55.

THE use of carbon-13 NMR spectroscopy as a routine analytical tool for organic chemists is now widespread. This book originated with a perceived need to incorporate this technique into the teaching of modern organic structure determination using the problem solving approach. The text is intended to be used in conjunction with several suggested references which provide compilations of standard mass spectral, infrared, proton NMR and carbon NMR data. It does not contain any introduction to the various techniques and is intended for those already familiar with the basic principles involved.

The book contains 125 unknowns which are comprised of the more common functional groups as well as some more unusual structures. Each unknown is allotted two pages containing its elemental analysis, infrared, 90 MHz proton NMR, 20 MHz carbon NMR and mass spectrum. Special proton NMR experiments such as D_2O addition or homonuclear spin decoupling and carbon-13 off-resonance decoupling experiments are included as inserts in the appropriate spectra. The unknowns are arranged on two facing pages so that all of the data for one compound may be examined without turning the page. The problems are arranged in order of increasing complexity of the molecular formula in a reasonably successful attempt to save the more difficult unknowns for later in the book. Isomeric structures are presented together to enable them to be worked on simultaneously. Immediately following the unknowns is an appendix containing a general approach to the solution of these problems followed by a detailed analysis of this approach as applied to ten selected problems of varying difficulty.

This book is a very useful text to incorporate into any course on organic spectroscopy. Although the authors state that it has evolved over a five-year period in a course taken by juniors, seniors and beginning graduate students, some of the problems are quite difficult and seem more appropriate for the latter two groups of students. Although concisely written, the discussion of the general protocol for solving organic spectral problems and the solutions to the ten selected problems are sufficiently detailed to take the student very clearly through the thought processes involved in deducing the structure from analytical data. Of particular note is the care taken by the authors to provide a feeling for which data are unambiguous and which data can be misleading. For example, they point out the dangers in assuming analytical "additivity" parameters are valid without the use of the appropriate model compounds. Similarly, they make note of alternative structures

where possible and suggest experiments to eliminate or confirm these.

Although the title of the book suggests that it is primarily concerned with carbon-13 NMR, in fact, equal attention is given to all of the techniques included in the problems. It is worthwhile remembering that the unknowns included in this text have already been "student tested" and found to be successful as a teaching aid. As a companion to one of the standard texts on organic spectroscopy this book is highly recommended. The answers are given to only ten of the problems which limits its value for independent study. If, however, the answers are obtained from the publisher, it would be very useful as a refresher to individuals already familiar with the analytical methods presented. □

Elizabeth A. Williams is an Organic Chemist in charge of the Nuclear Magnetic Resonance Facility at General Electric Corporate Research and Development, Schenectady, New York.

Stimulating sex hormones

R.J.B. King

Female Sex Steroids. By J.H. Clark and E.J. Peck. Pp.245. (Springer: Berlin, Heidelberg and New York, 1979.) DM 78, $43.70.

BOOKS can be categorized according to combinations of the four words useful, useless, boring, stimulating. The useful and stimulating category is all too small but this monograph decidedly falls into that group. It is the latest addition to a series that, with a few lapses, has maintained a high standard. The book is divided into 10 chapters dealing with the three aspects of oestrogen and progestogen receptors — namely methods of measurement (36 pages), intracellular characterization (99 pages) and physiological relevance (67 pages). The methodological section contains a series of recipes which, taken with the lucidity which graces the rest of the book, makes it eminently suitable for both

students and people wishing to initiate work in this area. On the other hand, the discussion of type I and II binding sites and the questioning of the basic dogma that steroids carry receptors from cytoplasm to nucleus make essential reading for *aficionados* of this area of endocrinology. It has been a feature of this series of monographs that the authors have communicated their own experiences within the given topic. The present volume continues this style with data, both published and unpublished, from their own laboratory blended with that of other workers. This is complemented by a catholic survey of the literature that makes the discussions and conclusions more formidable. I found this feature of the book particularly good because so many articles written about receptors for steroid hormones have taken a more parochial attitude. The main conclusions have been itemized at the end of the book. My own conclusion is that this is one of the best books yet written about the cellular endocrinology of the female sex hormones. □

R.J.B. King is Head of the Hormone Biochemistry Department at the Imperial Cancer Research Fund, London, UK.

European subnuclear physics goes American

THE news (page 122) that American subnuclear physicists wish to spend increasing sums on design studies for a new generation of accelerators — for fear of European competition — was aptly paralleled last week by an announcement from CERN, the European Centre for Subnuclear Physics near Geneva. It made official an earlier understanding that Professor Herwig Schopper, a Czechoslovak-born (but now German) physicist who is presently director of the German national accelerator laboratory, DESY, is to be CERN's next director-general. This should send a shiver up every American subnuclear spine.

Why? Because Schopper's reputation rests on transferring the 'American', pragmatic style of accelerator design to Europe, and specifically to DESY, the Deutsches Elecktronen Synchrotron laboratory near Hamburg. Moreover, DESY is an electron laboratory, specialising in accelerating electrons and their antiparticles (positrons) and colliding them with one another and with protons. CERN has been exclusively a proton accelerating laboratory, but has plans for building a giant electron-positron collider, LEP. To CERN, Schopper will bring not only his Americanism, but also his expertise in electron machine design — a problem quite different from proton machine design because of the low mass of the electron (1837 times less than the proton).

In the past America has taken a firm lead in subnuclear physics, starting with Lawrence's cyclotron (which created the pion) and the Berkeley Bevatron of the early 1950s, (which found the antiproton). At that time Europe was recovering from the Second World War, and it was a great feat of political will to create CERN just seven years after the war's end. It was initially a theoretical institute; ultimately accelerators were built, at CERN and in European nations, but always the US was in the lead. The first close race was in the early sixties, for the 'omega minus' predicted by Gell-Mann and Ne'eman's SU3 theory (which lead to the concept of quarks). The Brookhaven laboratory on Long Island won. Of the more recent fundamental discoveries — scaling in electron proton scattering (evidence for point-like quarks), of the J/psi and charmed quarks, of the neutral current weak interaction, of the 'upsilon' containing 'bottom' quarks — only one (neutral currents) was European, despite roughly equal spending on both sides of the Atlantic.

DESY, under Schopper's guidance, was the first to break this potential barrier, with the construction of PETRA, a 19 GeV on 19 GeV electron-positron collider, more than a year ahead of the American equivalent PEP. Unfortunately nature was not kind: there has been only one (contended) discovery, evidence for the decay of the 'gluon', the photon of the inter-quark force. The 'top' quark, possibly the last quark, is probably accessible to PETRA but it is still hiding. More significant was the way PETRA

was built — very fast, cutting all corners, finding money from all sources (including a federal budget for propping up an ailing civil construction industry). Schopper's objective was clearly to produce PETRA physics as fast as possible — not, as has arguably been the case with CERN, to produce beautiful accelerators that turn on at the switch of a button.

The interesting questions now are whether HERA, DESY's effort at a very high energy electron proton collider (to probe proton and quark structure), will go ahead so well without Schopper's guidance, and whether the 4000-staff, 12-nation CERN establishment at Geneva will respond as well as DESY to the Schopper shake-up. It is also interesting to see that Schopper's mentor in the US, ex-Fermilab director Robert Wilson, is also flexing his muscle again (he created Fermilab at breakneck speed and low cost and beat CERN to 400 GeV), and is talking of attaching electron rings to existing or planned American proton machines in a bid to beat HERA to its 1989 target. The game may be more even now than it was over the 400 GeV race (where there was a long European squabble over siting) because the sites for HERA and LEP are already agreed; and government money in the US and Europe for subnuclear physics is probably equally tight.

Schopper's plans for CERN involve an absolute minimum version of LEP, sparer even than the 'minimum LEP' defined by CERN design teams. His budget-LEP would just reach the predicted intermediate vector boson (a keystone of modern theories), but be capable of upgrading when the money is available. He also wants to bring the physicists and the accelerator design teams closer together, by encouraging more flexible arrangements for exchange of posts for limited periods. In CERN, the two groups have long been suspicious of one another. There is also a very active staff union, which may prove conservative; and there is the problem of 12-nation politics on CERN Council. It will be very interesting to see what Professor Schopper, who takes up his post on 1 January 1981, can do. We wish him well. □

Editor of Nature

Dr Peter Newmark, Acting Editor of Nature since the beginning of the year, hands over to John Maddox from the next issue. Dr Newmark remains Deputy Editor. Mr Maddox, Editor of Nature between 1966-1973 and lately Director of The Nuffield Foundation, resumed the post of Editor on 13 May.

United States

Physicists urge greater efforts on long-range acclerator research

HAVE US physicists become so engrossed in the short and medium-term challenges of the design of particle accelerators that they have neglected to give adequate attention to more long-term research needs?

The question is raised empirically by current delays in the production schedules of new accelerators at Fermilab and Brookhaven National Laboratories, at both of which the development of superconducting magnets is presenting more difficulties than originally anticipated.

And it is answered in the affirmative by the Department of Energy's High Energy Physics Advisory Panel (HEPAP) which is about to publish a 'call to arms' to the physics community warning that longrange research is ignored at its peril.

Currently such research consumes less than 1.5% of the total operating budget of the high energy physics programme. The panel is recommending that this be increased to about 4% — roughly $10 million at current levels — although aware that general budget stringencies make it unlikely that this figure will be realised in the near future.

The report has been prepared by a subpanel of HEPAP. It points out that impressive developments in accelerator technology — frequently based on ideas originating in Europe or the USSR but with their application refined in the US — have produced significant savings in the cost per unit of beam energy. But it also emphasises that the energy demands of physicists have been increasing even faster, roughly by an order of magnitude every seven years.

The net result is that the overall costs of new accelerators continues to rise. Any particular technological advance, such as beam focusing techniques or superconducting magnets, only have a limited effect on reducing costs. "Redoubled efforts" it says are therefore an "essential investment" if further technical breakthroughs are to be found which make the costs of new machines politically acceptable.

The total sums devoted to accelerator R & D are not large. But the money tends to be concentrated on specific projects, with even theoretical work dominated by shortterm goals. 60% of funds, for example, now go on research on the super-conducting magnets at Fermilab and Brookhaven.

Nor is there necessarily a manpower problem. Of about 1100 high energy physicists in the US, 200 are working fulltime on accelerator research. The report says that the supply of accelerator scientists, although marginal, is not critical.

"We are saying that the mechanisms for accelerator R & D funding are adequate. What is not adequate is the perception of need in the physics community," Dr Maury Tigner of Cornell University, chairman of the subpanel which produced the report, told HEPAP last week.

"This report is a call-to-arms to the field in general, pointing out that all of us have a problem. Sitting where we are today we can see the beginning of the end of the line of the current generation of accelerators; we want to encourage the community to start thinking about what happens next."

The report emphasises that international comparisons show western Europe and the USSR put more theoretical and experimental effort into long-range accelerator research. "The number of physicists available for this work is larger than in the US, and they are well supported," it says.

Among the areas that it suggests might benefit from increased funding are research on very high field superconducting magnets, on radio-frequency superconducting cavities, and on fundamental characteristics such as performance limiting phenomena.

It also recommends a substantial increase in funds for studies of new accelerator concepts. Among, these it lists laser-driven accelerators, and the possible use of linear accelerators with very high beam currents, currently being investigated for their potential use as particle beam weapons, but which have so far received little attention as tools for experimental physicists.

In the near future, however, the chances of increased funding for accelerator R & D look bleak. The operation of the three national accelerators is already being held back to meet construction commitments on Fermilab's energy saver/doubler and Brookhaven's Isabelle. And the Congress has high energy physics in view as one area to absorb a 'pause' in funding with no shortterm impact on the national economy.

Furthermore the Office of Management and Budget has always been reluctant to consider long-range research proposals, looking on them as, in the words of one energy department official, "the way in which we get pregnant with expensive accelerators". But even some politicians are becoming piqued at the US's loss of leadership to Europe. And this combined with the arguments that accelerator technology can have valuable spin-offs, may provide a counter-balance to budgeteer's fears.

David Dickson

Laying the foundations for ISABELLE: has the US lost its initiative?

New plans to catch the vector boson

EUROPEAN and American physicists continue to play cat and mouse with their plans for new particle accelerators. First it was over who will get first crack at the Z^0 particle, the neutral intermediate vector boson predicted by the Weinberg-Salam unified field theory.

Investigating the characteristics of the Z^0 — if it exists — is a prime goal of the Large Electron Position ring (LEP), proposed for construction at the European Centre for Nuclear Research (CERN) with earliest possible completion planned for 1986.

Rising to the challenge, physicists at the Stanford Linear Accelerator Center worked out a way they could adapt their machine to produce single collisions beteen bunches of electrons and positrons at the 90 GeV range where the Z^0 is expected to be found, thus beating the Europeans to the mark.

CERN, under strong prompting from its director-general elect Dr Herwig Shopper, responded by pushing forward plans for LEP so that it could become partly operational by 1986, thereby closing and possibly eliminating the gap with the US.

Now US physicists are suggesting another tack, proposing that if the Z^0 race is conceded to Europe, it might make more sense to try competing in a different area, namely by constructing a machine to examine electron-proton interactions.

In Europe, where theoretical physicists have been supporting the study of electronproton interactions for some time, such experiments will be carried out on Germany's proposed HERA accelerator in Hamburg. The construction schedule for HERA, however, which has still to be approved by the German government, would start with electron-electron interactions, not bringing the proton ring into operation until 1988 or 1989.

Some US physicists are arguing that, if an electron storage ring can be attached to one of the existing proton accelerators, they could get there considerably sooner, perhaps even by 1983.

Specific proposals about how this might be achieved using either Fermilab's Tevatron or Brookhaven's Isabelle have been drawn up at Columbia University under the enthusiastic guidance of Dr Robert Wilson, ex-director of Fermilab.

According to Dr Wilson, the physics possibilities, which include the study of interactions with polarised electron beams, are 'substantial'. He also argues that an electron-proton collider is "competitive with more expensive projects" — a crack at the SLAC proposal which is likely to cost two or three times the $30 million he says the electron-proton project needs for "a modest experiment at low energy".

Fermilab scientists, initially sceptical about the practicality of adding an intersecting electron ring, have carried out their own calculations and found the technical aspects relatively straightforward.

Scientists at Columbia are enthusiastic about the idea. They suggest that although considerable uncertainty exists about what might be found, electron-proton interactions could help elucidate the structure of quarks. They might even, according to Dr W Lee, provide under certain conditions a quark 'factory'.

Enthusiasm for such a project has also come from Canada, where physicists have independently been working on their own proposal to add an electron ring at Fermilab.

A steering committee has been set up for what is known as the Canadian High Energy Electron Ring (CHEER), and it is intended to present a feasibility study for a project costing about $50 million to the Canadian government in September.

There could even be scope for Japanese participation. Japan already has provisional plans for its own electron-proton machine. But this would not be built for some time; and meanwhile some physicists are arguing that there is scope for a multilateral project drawing on the resources of all three nations.

Physicists less directly involved are more ambivalent about the proposal. They accept the argument that if Stanford's experiment only precedes the broader-based European experiments by a year or two, there may be little advantage in duplicating efforts. However, many feel that recent advances in high energy physics indicate that electron-positron scattering could prove a more fruitsul direction that stabbing in the dark with electron-proton collisions.

The picture is further clouded by the informally-announced intentions of Cornell University to develop a rival proposal to SLAC for raising the energy of its electron storage ring (CESR) to the range where the Z^0 particle is expected to be found. So, if funds for a new construction somehow materialise in next year's HEP budget — at present a rather faint possibility — intense competition can be expected for the direction in which they will be allocated. □

Academy to examine US links with European and Japanese scientists

FINANCIAL stringencies have reduced the contact of US scientists — particularly those at an early stage of their careers — with colleagues in other western countries precisely when these countries are beginning to catch up and occasionally surpass the US in scientific capability. This trend is worrying some US scientists. The National Academy of Sciences is therefore setting up a new committee on international human resource issues to look at the obstacles to closer links between US scientists and their colleagues in western Europe and Japan.

Academy officials say that the need for such a study comes more from a general impression of declining contacts than from any body of hard data. But they point, for example, to a recent NAS study which showed that there was a 55% drop between 1971 and 1977 in the number of new PhDs in science and engineering — indicating a firm commitment to postdoctoral study abroad.

The numbers involved are not large; in 1971 the total number was 409, and by 1977 this had fallen to 147, a decline from 2.4% to 1.2% of the total PhDs. But the trend this indicates is confirmed by more anecdotal evidence of the low number of US scientists to be found in most European laboratories, and the decreasing tendency to request foreign travel funds as a component of applications for research grants.

Academy President Dr Philip Handler warned the academy's members at their annual meeting in Washington last month that although small science in Europe seemed to be suffering the same financial pressures as in the US, cooperation in big science was proceeding rapidly, with potential implications for trans-Atlantic scientific relations.

"As their common strategic planning waxes, the strength of their scientific relations with this country will undoubtedly wane unless we exert special efforts," Dr Handler said. "That makes particularly ironic the decline in the number of young American scientists who can arrange meaningful experiences in European laboratories — where the benefits of such experience are now larger than ever."

Dr Handler said that he had asked the academy's foreign secretary, Dr Thomas Malone, to take a closer look at the changing relationships and "to ascertain whether we are losing touch with European science and whether any important trends may be discerned."

The chairman of the new committee is Dr Walter Rosenblith, Provost of the Massachusetts Institute of Technology, and funding for the committee's work is currently being sought from a number of government agencies and private foundations.

If appropriate funds are forthcoming, the committee will initially set up a number of working groups to examine issues such as the funding of foreign travel by US scientists, and the effects of national taxation, employment and immigration policies on scientific exchange. The focus of the committee's work xill be on links with western Europe and Japan, possibly including other western industrialised nations such as Australia, but omitting either the USSR or the Third World.

Dr Rosenblith said last week that a proper study could not be carried out by the US alone, but would benefit from the active participation of other nations, either individually or through organisations such as the European Science Foundation. "It is a question of the general rationalising of resources" Dr Rosenblith said. "We want to be sure that science as an international activity does not become too fragmented."

David Dickson

US signs scientific cooperation agreement with Japan

PRESIDENT Carter and Japanese Prime Minister Masayoshi Ohira last week signed a five-year agreement covering cooperation in scientific and technological research between the US and Japan.

In addition to encouraging more conventional forms of scientific exchange, the agreement provides a framework for the development of joint research projects between the two countries, and follows an earlier agreement on energy research which was signed in Washington last May.

Officials from both sides have identified 40 projects on which possible collaboration is now being investigated. These include the use of recombinant DNA techniques,

particle accelerator research, and studies of the detoxification and disposal of hazardous wastes and the climatic impact of increased carbon dioxide concentrations in the atmosphere.

One area in which plans for bilateral co-operation are already well advanced is in space research, where agreement in principle has already been reached for collaboration on 17 projects, and has formally been signed on nine. Areas of joint collaboration include the study of plasmas close to the Earth, and projects for a possible mission to rendezvous with the Comet Halley, and to send a joint orbiter and probe to Saturn. □

France

Biotechnology company planned

A French banking consortium intends to create a company called Transgène to develop commercial applications of genetic engineering. Although plans have not yet been finalised, the consortium, known as Paribas, is expecting initially to invest about £8 million in a five year programme of research.

In addition to its own laboratories, Transgène is likely to have close links with universities and government research institutes. Paribas are negotiating the financial and legal aspects of such links and are said to favour a scheme in which collaborating laboratories and institutes would be rewarded with shares in the company.

Negotiations appear to be complicated by the involvement of many of the French scientists with relevant expertise in a public sector organisation, G-3, set up over a year ago because of the lack of private investment in biotechnology. G-3 is financed and run chiefly by the Institut Pasteur and the Centre National de la Recherche Scientifique, with minor contributions from the Institut National de la Santé et de la Recherche Médicale and the Institut National de la Recherche Agronomique. It has a laboratory and about five scientific staff at the Institut Pasteur and will be spending about £0.3 million this year, much of it on the development of a vaccine against hepatitis B.

A further complication may arise from the possible role of Institut Pasteur Production (IPP), the commercial arm of the institute. At first IPP had preferential rights on any successful G-3 project, but that arrangement no longer exists. The future of IPP is currently unclear, following the breakdown of long and complex negotiations over a merger with two French pharmaceutical companies, l'Institut Merieux and Rhone-Poulenc; a possible merger with Sanofi, a subsidiary of the oil company Elf, is now being negotiated. To close the circle of negotiations, a report in *Le Monde* suggests that Sanofi is also considering joining Transgène.

Given the limited number and prior involvement in G-3 of French scientists with expertise in genetic techniques it is likely that Transgène will recruit internationally. It remains to be seen whether they will be able to attract such a large number of good candidates as has the Geneva-based company of Biogen, which has just appointed the first director of its scientific laboratory (*see below*).

Meanwhile the UK National Enterprise Board continues to contemplate the creation of a publicly-owned biotechnology company. Although enthusiasm for the idea is said to be high within the NEB, hopes for an early decision have abated probably because of pressure to involve private industry in the proposed company.

● Julian Davies, Professor of Biochemistry at the University of Wisconsin, is to be the first director of Biogen's laboratory in Geneva. A British-born and -trained biochemist, Professor Davies is best known for his work on the mechanisms of bacterial resistance to antibiotics.

Peter Newmark

United States

Solar Polar Mission threatened

EUROPEAN space officials travelled hastily to Washington last week in an attempt to prevent the US Congress from killing the International Solar Polar Mission, a joint effort by US and European scientists to send two spacecraft in complementary orbits around the Sun.

The mission was originally scheduled for launch in 1983, jointly funded by the National Aeronautics and Space Administration and the European Space Agency. Last month, reflecting moves to balance the federal budget and find additional funds for the much-delayed space shuttle, NASA announced that the launch would be delayed until 1985.

Now a Congressional Committee is recommending that the mission be abandoned. In passing NASA's request for further support for the space shuttle in the current financial year, a House Appropriations Subcommittee has suggested that $15 million be cut from the ISPM's budget of $47 million — and that the mission should be terminated.

It was the same subcommittee, chaired by Edward Boland of Massachusetts, which three years ago almost succeeded in killing the Galileo mission to Jupiter. No comparable move to cut the ISPM is likely in the equivalent Senate Subcommittee, which has a number of ardent space supporters, including ex-astronaut Jack Schmitt. But a fierce fight seems likely when House and Senate meet to resolve their diferences over NASA's budget.

Current plans for the solar polar mission are that the two spacecraft will be launched simultaneously to fly over the sun's poles in opposite directions. It would be Europe's first deep-space mission, and contracts for $56 million were awarded last year for spacecraft development and manufacture to Dornier, chief contractor for the multi-national STAR consortium.

The ISPM has been allocated 20% of the ESA's current science budget. European officials have pointed out that it is now too late to allocate the funds to other projects. □

Canada

33 percent boost for research

CANADA'S new liberal government has, as expected, endorsed the substantial growth in support for basic research promised by the previous conservative government shortly before it was defeated in the general election last February.

Mr John Roberts, the Minister of State for Science and Technology, announced last week that the Natural Sciences and Engineering Research Council (NSERC), the largest of the three research councils, will receive a 35% increase in its 1980/81 budget over the current year. This will bring the research council's total budget to $162.6 million.

The NSERC increase is precisely the figure announced by Mr Robert's predecessor, Mr Howard Grafftey, in January, and is based on a five-year plan which the research council submitted to the government last year. The Medical Research Council will have its budget increased by 17% to $8.2.2 million, and the Social Science and Humanities Research Council by 16% to $41.7 million.

In announcing these budget increases to the Canadian Association of University Research Administrators, Mr Roberts also said that the liberal government remained committed to its goal of raising the amount of the gross national product devoted to R&D from 0.9% to 1.5% by the mid 1980s. However to keep in line with this will, he said, require the government to find an extra $30 million for R & D in 1980/81 over and above the total increases of $155 million already announced.

Canadian scientists, who have criticised the decision of Prime Minister Pierre Trudeau not to emulate the conservatives by appointing a minister with special responsibility for science — Mr Roberts also holds the portfolio for mines and energy — have nevertheless been cheered by the announcement that promised that funding increases will be honoured.

The Canadian government is also expected to announce shortly that it is setting up a high-level committee to examine how Canada should pursue its involvement in the field of biotechnology.

A study that has been prepared by the Ministry of State for Science and Technology shows that although various research programmes are currently underway — ranging from research on the cloning of insulin genes to studies of nitrogen fixation — they are widely dispersed and often lacking in depth.

For example, although about 100 university scientists are currently involved in biotechnology research, they are divided between 22 universities. Similarly of over 33 firms in the field, only ten have more than one or two research workers involved.

David Dickson

The Netherlands

Tilting back to windmills

The old Dutch windmill . . .

THE windmill is a traditional feature of the Netherlands landscape; but now there is a new turn for it as an energy source. The Netherlands government is carrying out a multi-disciplinary study, and a plan has been put forward for a large wind-and-water power scheme for electricity generation in the unreclaimed part of the Zuiderzee.

The plan comes from hydraulic engineer L W Lievense, and would not reclaim the 40,000 hectare Markerwaard area, but convert it into a huge storage reservoir behind 15-metre dykes, on which would be mounted 400 wind turbines generating 1 to 1.5 MW. The turbines would pump up to 30 cm of water a day into the lake, from which water would fall 12.5 metres at four points in the dyke to drive 160 water turbines, generating 10MW each. At night, a third of the water turbines would themselves pump water into the reservoir, doubling the inflow to 60cm a day. Mr Lievense claims the scheme would generate 10% of national electricity demand at a
. . . and the new: a wind turbine due to come into use this year

capital cost of 3,000 million guilders.

Six government departments are involved in preparing the Lievense scheme, and the first detailed study is expected in August. There are ecological objections to it: lack of sunlight in the deep water would kill organisms on which fish life now depends, and fewer fish, together with the strong currents caused by the overflow points would threaten bird life.

Wind energy is generating great interest in the Netherlands: a private study has calculated that small private 10kW turbines could supply half the electricity needs of groups of 20 houses.

The government's own wind energy research programme is mainly directed to large-scale application. When the programme was started in 1976 it was thought that 5,000 windmills could generate up to 15% of national electricity. Now estimates have been cut back, due to the cost and difficulty particularly of building the offshore windmills envisaged earlier. But the government still believes that 500 turbines could generate up to 2,500MW a year, saving a million tonnes of oil equivalent. **Caspar Schuuring**

Australia

Probe into A-bomb test deaths

THE South Australian Health Service has sent a team to check on reported deaths and blindness suffered as a result of two British atomic bomb tests in October 1953. Members of the Yankunyatjara ethnic group of Australian Aborigines claimed that several of their people became ill or died when a "rolling black mist" enveloped their homes in Willatinna, 45 miles north of the Emu atomic bomb test field. Witnesses claimed the tests resulted in the blindness of 45 people, including many otherwise healthy children, as well as uncontrollable diarrhoea, vomiting and skin rashes. It is also claimed that older members of the group started dying within five days of the tests.

A former sheep station owner in South

Australia, has confirmed the report; she says she saw the cloud, which left an oily dusty residue on buildings and fruit trees, which later died. Her husband died from liver cancer in 1964.

The investigation comes on the heels of public protest about cancer deaths among workers and soldiers at nuclear test sites. The South Australian Campaign against Nuclear Power says that a large amount of low level nuclear waste was left behind at the test site and has only recently been fenced in, with warning signs in English which the Yankunyatjara cannot read. The Australian Veterans' Association has demanded immediate government action to clean up the site and compensate the victims of the exposure. □

United Kingdom

Scientists' union says nuclear inspectors are under-staffed

THE Institution of Professional Civil Servants, the trade union for government-employed scientists, released a document last week criticising the government for allowing staffing levels in the Nuclear Installations Inspectorate to fall 22 members short of its complement of 104. The NII no longer has a fracture mechanic specialist to assess the potential for fast fractures in pressurised water reactor vessels, an important aspect of PWR safety (*Nature,* 28 February, page 804). In addition, a single nuclear inspector has covered two power stations, Calder Hall and Chapel Cross, since December. In spite

of heavy advertising over the last two years, only two suitable candidates have been found for the 22 vacant posts.

An official with the Health and Safety Executive conceded that the shortages were serious, but said that adequate safety levels were baing maintained on a short-term basis. On the question of fast fracture analysis, the Executive says that it has the capacity to make the analysis, but that it may have to subcontract the work to the Safety and Reliability Directorate of the Atomic Energy Authority in the case of "unforeseen occurrences". Mr F R Mullin of IPCS said this would compromise an

independent analysis of PWR safety, and IPCS members in both the NII and the AEA would not cooperate with a sub-contracting policy.

The UK Secretary of State for Employment has revealed that of the six Health and Safety inspectorates (agriculture, alkalis and clean air, factory, mines and quarries, and nuclear installations) only the NII has been permitted to decline in strength. Since 1977, overall HSE, staffing levels have increased by 6%, while in the NII they have declined by 21%.

Joe Schwartz

NEWS IN BRIEF

Stanford's success with colliding beams

PHYSICISTS at the Stanford Linear Accelerator Center California, US, have reported that they have successfully generated collisions between beams of electrons and positrons on the new Positron-Electron Project (PEP), now nearing completion at a total cost of $78 million.

The initial collisions were carried out at an energy of 16 billion electron volts. Eventually PEP will be producing collisions at 36 billion electron volts, and at this energy it is hoped that it may have more success than the German PETRA machine, which came into operation last year, in seeking the sixth quark.

Although plagued by both political and construction delays — and by the shortage of qualified technicians on the West Coast — operation of the colliding beams occured only a few months behind schedule. However the delays have meant that European scientists are about a year ahead in operating colliding beam machines.

NSF to investigate handling of MIT patent

THE National Science Foundation is to investigate whether the Massachusetts Institute of Technology has properly exercised its responsibilitites in licensing the results of research into magnetic filters supported by NSF funds.

MIT has offered Magnetics International of Ohio a non-exclusive license on the high gradient magnetic separator. However, the company wants better terms; and it has asked the NSF to judge whether the arrangement proposed by MIT is "reasonable under the circumstances".

Under the terms of the current institutional patent agreements between the NSF and universities, the Foundation has "march-in" rights to determine whether a university is doing its best to ensure that the results of the research are reaching the market-place.

The Foundation has published a notice in the *Federal Register* announcing its intention to exert these rights, and to evaluate whether current patent law allows MIT to retain exclusive rights to the patent. A public hearing will be held next month.

US backs off non-proliferation stance

THE US State Department made it known last week that President Carter had decided to support the export of 38 tons of enriched uranium to India, even though Prime Minister Indira Ghandi has refused to make any commitment to halt further nuclear tests.

A request for an export license for the uranium, to fuel the power station at Tarapur, is being considered by the Nuclear Regulatory Commission. Under the terms of the Nuclear Non-Proliferation Act of 1978 — largely drawn up as a result of earlier nuclear tests by India — the NRC cannot grant a license if the recipient country has not signed the Non-Proliferation Treaty, or agreed to accept international inspection of its nuclear facilities.

Despite India's continued refusal to observe either of these conditions on the grounds that they represent interference in the country's internal affairs, State Department officials say President Carter is likely to overrule the NRC's expected rejection of the license application. They argue that the political stability of the near East is more likely to be maintained by keeping on good terms with India.

In a separate decision taken last week, the NRC has agreed to permit the export of a 625 MW nuclear power station to the Philippines, despite objections that the reactor is to be built on the slope of a non-active volcano and in a known earthquake zone. Three of the five commissioners found that the Westinghouse reactor did not pose an unacceptable risk to the "global commons" of the oceans or the atmosphere. Considering earthquake risks did not come under their mandate, the commissioners decided.

"Ten to one the reactor goes first!"

UK unions to make independent dioxin study

Two of the UK's largest unions are to make independent assessments of the effects of dioxin exposure on their members employed at Coalite and Chemical Products Ltd in Bolsover, Derbyshire. The unions have questioned a report prepared by the Health and Safety Executive that found no long-term differences between workers exposed to dioxin as a result of an explosion in 1968, and a control group of management personnel (*Nature,* 6 March and 1 May 1980). The Association of Scientific, Technical and Managerial Staffs has screened 21 of its 300 members at the plant for liver and heart conditions, and the Transport and General Workers Union will check a sample of 35 members for dioxin effects.

In the meantime, the EEC Commission is to conduct an enquiry into 2,4,5-T, the dioxin-containing weedkiller. The Commission, which has the power to ban the use of dangerous substances, was pressed into the investigation by Mr Ken Collins, a UK member of the Labour group in the European Parliament after he received a dossier on the chemical from the UK National Union of Agricultural and Allied Workers, which was instrumental in getting the chemical banned by the Trades Union Congress early this year.

Soedjatmoko to head UN University

MR K. Soedjatmoko has been appointed Rector of the United Nations University in Tokyo. A specialist in Southeast Asian and Indonesian social, political and cultural development, Mr Soedjatmoko, aged 58, is currently adviser to the National Development Planning Agency for Social and Cultural Affairs of Indonesia. He was Indonesia's ambassador to the US from 1968-1971. Mr Soedjatmoko is involved with a number of international development research organisations, including the Ford Foundation and the Club of Rome.

Bondi to chair environment research council

SIR Herman Bondi has been named the first full-time chairman of the British Natural Environment Research Council (NERC). The appointment, announced last week by Mark Carlisle, Secretary of State for Education and Science, will be for four years starting 1 October 1980. Under a major administrative rearrangment, Bodi will replace the present part-time chairman, Sir James Beament, as a full time executive and accounting officer. The change, and the appointment of Bondi, presently Chief Scientist at the Department of Energy, is expected to make the NERC more effective in carrying out its programme of investigation of nuclear waste disposal problems, one of its primary tasks. Bondi will continue to hold his job as Chairman of the Advisory Council on Energy Conservation.

Taking an 'all round attitude' to science

Indian Prime Minister Indira Gandhi (right) takes a keen interest in the development of her country's science and technology. Here, she talks to **Anil Agarwal**

DISCUSSIONS at the United Nations Conference on Science and Technology for Development held in Vienna last year revealed that few Third World leaders take an active interest in the scientific and technological development of their nations, and this is a constant complaint of their scientists. Prime Minister Indira Gandhi of India is an exception. She holds direct charge of the Indian government science and technology, atomic energy and space and electronics departments, and is also President of the Council of Scientific and Industrial Research (CSIR). In effect she is India's minister of science and technology. Why with all her other duties as the chief executive of a state, should Mrs Gandhi take on this role? Her reply is simple: "Because the scientists think that it's important. They think that they are then much freer of the bureaucratic stranglehold." This direct access to the top has made Indian scientists the envy of their counterparts in many Third World countries.

Prime Minister Indira Gandhi recently called a meeting of selected heads of scientific institutions to discuss problems faced by India scientists. The government may soon issue a statement to scientists emphasizing their role in national development. Mrs Gandhi herself has suggested that science and technology planning should be extended beyond central government. She would like committees such as the National Committee on Science and Technology — the existing policy-making institution of the central government's Department of Science and Technology — to operate at state government and, if possible, district level. Young scientists with suggestions for new uses of science and technology for development could be included on these committees.

Environmental problems

As well as her interest in the role of scientists in development, Mrs Gandhi also takes a keen interest in the related issue of the environment. She recently released the World Conservation Strategy prepared by the International Union of Conservation of Nature and Natural Resources, and called a private meeting of Indian ecologists to discuss environment. It is a concern she says she was born with. "I happen to deeply love the earth, and I have

from childhood been concerned about the cutting of trees. I sympathise with Bernard Shaw when people asked him why don't you keep flowers, and he said that I love children but I don't chop off their heads and keep them in my drawing room. So that's the sort of outlook I have always had. The aesthetic point of view is very much there. Most urban life is an uglification. To me personally this is the more serious aspect.

"Now we find that progress itself and the use of science and technology is creating its own pollution, which is very much worse. Just yesterday I read in *Time* magazine of this chemical that was sprayed in Vietnam and now all the children have been born deformed, apart from the fathers being diseased. Now that is all part of pollution. We are completely dependent for our very survival on at least air and water. And if those are going to be dirty or polluted, then mankind can't survive. Now I said somewhere that I don't know if it is important for it to survive or not. Presumably most people want it to survive, so I suppose they should pay greater attention to it."

In India there has been considerable interest in the extensive deforestation that has taken place in the Himalayas. There are two philosophies about its causes; one is that pressure of growing population is leading to deforestation; the other is that a wrong development strategy, which has failed to attack poverty, has led also to environmental problems.

According to Mrs Gandhi "it is much easier to cut trees than to grow them. This

process started in a very, very big way during the Second World War, and people did get the mentality of thinking of forests only either for timber or for industry, paper industry or something else. All of which is destructive. Whereas you can have what is called forest farming or social forestry, and so on. But it is true that when you make plans you don't think of every aspect of it. You think these people are poor, they need jobs and you need such and such goods, and you then have a proposal which will try and do both things. Until a decade or so ago, nobody thought about the environment or other aspects. I was just reading in a health magazine that even the effect of a very good programme such as bringing water to an arid area can bring disease to which the local people are not immune if you are not careful about it. So it means that you have to be all the time on your toes and keep looking at the problem from all around." Indian scientists have sometimes failed to display this "all round attitude", she complained.

In the Himalayan region of the State of Uttar Pradesh, local villagers have launched a unique movement against the state government sponsored auctions of vast tracts of forests. For several years they have prevented felling by hugging the trees — hence, the movement's name: Chipko Andolan, the hugging movement. To what extent does Mrs Gandhi appreciate such a popular movement? "Well, frankly, I don't know all the aims of the movement," she replied diplomatically. "But if it is that the trees should not be cut, I'm all with it." But the movement is also concerned about

A new improved camel cart with rubber tyres

the poverty in the region. "Naturally, anybody who lives in an economically backward country has to be concerned with that," she argued. But emphasizing the importance of trees in themselves, she added; "the cutting of trees has immediately brought havoc because it has increased our drought, it has increased our floods. And it has made vast areas much more difficult to live in."

What about the energy needs of the very poor who subsist on fire wood? "We are taking up a massive tree plantation programme," she says. "In it, we have also said that all aspects should be considered; food, for instance. Where fruit trees could grow we should try and emphasize that. And quick growing trees which could finance the programme (and be used for fuel), and longer growing trees which you need for other purposes. But, of course, you can use other things for fuel. Even in forests you can use various things which can be dried and used."

She believes a more imaginative approach is needed for this problem. The Planning Commission is considering setting up a National Ecodevelopment Corporation to assist local communities to take up extensive tree planting.

Oil and alternative energy

The energy problem is "very serious just now for us", says Mrs Gandhi. An overwhelming proportion of India's export earnings are being used to import fuel and fertiliser, because of the increased price of oil. Future rises could make matters worse. "Although we have oil," explains the Indian Prime Minister, "it is only lately that we have started trying to get it out, and even that is a very expensive process. (Most recent oil discoveries in India have been offshore.) Now we are experimenting with solar energy, we are experimenting with wind energy; in some parts, it has been successful, but we haven't tried it on a big

scale. So we are trying everything possible, any new idea that comes."

But wouldn't the further spread of the energy-intensive 'green revolution' exacerbate the energy crisis? Indian farmers last year suffered a crippling diesel famine and their irrigation pumps remained dry just at a time when the country was witnessing its worst drought of this century. India had no choice but to initiate the green-revolution-type of agriculture, believes Mrs Gandhi. "It was a time of acute grain shortage, and the point was how do we immediately double the production of wheat. And so we went all out, and that is how we have been able to survive all this time, even through other droughts. It's true we went a big way into diesel because we even transformed our railways. So now we have to see other forms of energy."

Commercially viable solar energy may soon be a reality which could make a big difference to India, believes Mrs Gandhi. But there have been arguments over imports of solar technology. The scientists at the state-owned Central Electronic Ltd who have been coordinating India's R&D on solar cells have strongly protested against the efforts of a private Indian company to manufacture solar-powered pumps with imported solar cells in collaboration with a US company. "We are never allergic to importing anything that we really need," Mrs Gandhi says. "What we have to ensure is that it doesn't hit our national interest in any way. And if we are making that thing in India, obviously it is better to have that even if it is a little inferior. But if we don't have it and it is going to help the people, then we have never hesitated."

The US federal budget alone for solar research in 1979 was more than the entire R&D budget of India in that year, I pointed out. The gap between the size of the two efforts was so big that it was certainly very

difficult for Third World scientists to keep up with R&D in the West. "It is very difficult to keep up, and yet our scientists are doing a very good job," she replied. "No, I don't think that the gap matters much. We are not competing with R&D in the West. It is much more important to have a solid base than to just have a very sophisticated top, which is, for instance, what Iran did. So from that point of view, even to be able to digest the knowledge that other countries are producing, you have to have a base. You can't have a base unless your scientists have the opportunity at every level of experimenting and of trying out these things. So it has to be a mixture. If you feel there is something that will help your scientists if you take it from outside, then you should take it from outside, providing that country is not going to use that as a foothold to influence other policies."

The Indian Prime Minister believes in the need to conserve energy and respect old, culturally-accepted energy-saving technologies. "All the new houses," she points out, "are built for energy consumption. They are hot in summer and cold in winter, whereas our old houses are not. The ancient house in which I was born and lived contained no cement, so probably it was cheaper to build. It never leaked in my memory. But when this house came under the purview of the Jain Fund, they said Oh! the ceiling might fall on the children because it was a children's home. So then they got engineers and they found it was only made out of bran and lime and various things like that, and it was at least 100 years old then. But it has never fallen yet. So we have not only to have new technology, but look a bit to the old technology. There is much sense in what people have evolved over the years to suit their climate, their environment their way of living. You can't keep all of it, because our way of life has changed, but I think a lot of it can be adapted and made more efficient."

Appropriate technology is important

But in contrast to the previous administration, Mrs Gandhi has been described as a critic of small-scale, village-oriented "appropriate technology". Did she think it was important? "I think it is very important," she immediately replied. But added a note of caution! "I don't think it excludes the other. I think that we have to have a mixture of cottage industry, village industry, small-scale industry, medium industry and heavy industry. Without heavy industry we cannot keep our freedom because we would be completely dependent on other countries. But we certainly can't survive only with heavy industry. So it is a question of encouraging things all along the line. For instance, take a bullock cart. Now you would like the farmer to advance from the bullock cart, but until we can advance, I would rather

that he had tyres on the bullock cart than we ignored it altogether.''

India is attaching a lot of importance to bio-gas plants, pointed out Mrs Gandhi. She admits, however, that they are acquired by rich farmers only. ''I'm sorry to say this happens in every field, no matter what you do. The people who are more powerful — even at the lowest level — are the ones who somehow grab the advantage. And with biogas what has happened is that the poor person who was getting the cowdung free, no longer gets it (after the introduction of bio-gas plants) as it becomes a commercial item. And, its the same with wood. We find the same thing happening with our fishing. We introduced deep-sea fishing, and here I must say that at least I was aware from the very first discussion on buying trawlers. I said well what are we going to do about the existing fishermen. The others assured me that they would be assimilated, they would be trained and so on, and that all the area closer to the shore would be theirs. But, in fact, it has not happened and they have suffered.''

What then can be done to ensure that the introduction of new science and technology does not worsen the lot of the poor? ''There is nothing much you can do about it,'' answered Mrs Gandhi, ''except where you find this happening you do something to help those who are being neglected.''

How can a developing country like India respond to the rapid advances in electronics which are bound to have an enormous impact? ''In India I would say that if you found that a computer made a lot of difference to efficiency you should get it. Where there is greater efficiency and greater production, that automatically makes for more employment. Even in farming where the agricultural production has gone up, it has not made for less people working. They need more labourers and they are able to pay them higher wages. I don't think that in any of these modern technologies there is a basic conflict provided you are all the time seeing what harm it can do either to health or employment or the poor or whatever it could be. You should be all the time willing to change if you find that it is not functioning as it should.

The bureaucracy in Mrs Gandhi's scheme has to play a major role in protecting the poor from the vagaries of modern technology. Now this is where we come up with a difficulty with government action. Somehow the bureaucracy — and even the brightest of them — likes to go along a set path and they feel that if there is a little deviation somehow heavens would fall or something.''

North-South and South-South relations

The recent Brandt Commission report on North-South issues has voiced some of the beliefs of Third World leaders like Mrs

Gandhi: that the economic development of the South is in the interest of the North and that part of aid should be in the form of an international tax. But she says she hasn't yet read the report carefully. ''I have just flipped over pages. Most of it depends on the Group B countries (UN language for western countries) and this is the trouble — the difficulty rather — that these are the countries that don't want to move. So where do we go from there?''

Can the developing countries get together to increase their bargaining position with the North? There is much talk in the UN, for instance, about technical cooperation amongst developing countries. ''This is what we are trying to do. This was our effort in the non-aligned movement,'' she says. ''In each of them — Lusaka, Algiers, Colombo — we had to go further along in that direction. The trouble is that we are very bad propagandists, we just don't know how to sell ourselves and what we are able to do in this country. When most people come to India they would rather go and see the Taj, so that even when they come here they don't return with very much more knowledge.''

There were a number of examples, said Mrs Gandhi, where India had obtained a contract from another developing country

only after it had been broken with a western country. Third World countries still look mainly towards the West. However, the developing country, she said, remarked: ''how much better it was, and how satisfied they were and they hadn't realised that (a) we could do the job and (b) because we ourselves came from a similar economy we would know and understand their difficulties and what they wanted to do much better.''

Now that Indian companies have started operating in various Third World countries, did the Indian Prime Minister think there was any way by which countries like Tanzania or Zambia could ensure that the commercial operations of Third World companies led to increased self-reliance of the host countries instead of increased dependence as happens with the operations of multinational corporations? ''Obviously, I would like them to grow keeping the national interest in view,'' she replied. ''The tendency as you saw in the report on ITT is that the multinationals think of profits first and everything else second and third. For the developing countries, joint ventures are a useful way of cooperation.''

As the Indian government restricts Indian companies from investing capital

Baking wood to make charcoal (above): tree denuded of its branches (below) which are removed for firewood.

abroad, many operations abroad are indeed joint ventures gained on the strength of Indian know-how.

What will her own administration's policy be towards the multinationals? Contrary to some suggestions in the Indian press that her government may be more receptive to multinational investment, Mrs Gandhi replied: "Generally, we are not for multinationals. It depends, however. If by multinationals, you mean only the very big concerns, then we would rather steer clear of them. But there are areas where you can't like oil drilling. Or there are areas where it doesn't matter. Suppose they made Coca-Cola here — I have never even tasted it — I don't think it matters much because it is controllable. You have to look at these things individually, but generally speaking we would rather not get involved with them." Coca Cola and IBM were the two leading western companies that had to wind up their operations in India during former Prime Minister Desai's administration.

Nuclear energy

Finally, a word about nuclear technology. Did she in any way share the growing concern in the West about the feasibility and safety of nuclear technology? "On the other hand," she countered, "in Sweden they voted for it."

Mrs Gandhi has been a strong supporter of India's nuclear programme and its objective of achieving self-reliance. But she says she "can't prophesy anything at this stage" about whether India could achieve that self-reliance in the face of difficulties and delays in its nuclear programme. She did feel that India should put some, if not all, effort in achieving this aim. "We are using it for agriculture and various other things".

Mrs Gandhi did not know when India would receive deliveries of enriched uranium fuel from the US for the Tarapur Atomic Power Station. India has maintained that the US has to supply nuclear fuel under an agreement that came into force in 1963 which cannot be changed unilaterally. She is still extremely critical of western efforts to restrict the spread of nuclear technology. "It is the whole attitude of not allowing the developing to develop more. Once somebody has atom bombs, they are willing to accept it, they don't mind," she says, probably referring to western acquiescence over China's acquisition of the bomb. "They don't want us even to have peaceful explosions, when we have made it very clear that we are not going to make bombs or stockpile any kind of nuclear armaments."

The US administration last week announced that they were asking the US Nuclear Regulatory Commission to send two further shipments of nuclear fuel to India even though it has not signed the Non-Proliferation Treaty. The political sensitivity of the region because of Afghanistan was cited as the reason. □

Two by two

THE teaching of evolution in American schools has long been slowed by a successful campaign that demands "equal time" for an alternative theory of origins. The leading organization in this effort (advertised in *Nature* p.vi 21 February, 1980) is the Creation Research Society (CRS). In 1972, all members subscribed to the Statement of Belief, the first three paragraphs of which are:

● The Bible is the written Word of God, and because it is inspired throughout, all its assertions are historically and scientifically true in all the original autographs.

● All basic types of living things, including man, were made by direct creative acts of God during the Creation Week described in Genesis. Whatever biological changes have occurred since Creation Week have accomplished only changes within the original created kinds.

● The great Flood described in Genesis, commonly referred to as the Noachian Flood, was a historic event worldwide in its extent and effect.

The Creation Research Society does not promote alternatives to evolutionary theory in other religions. Many readers of the first chapter of Genesis have interpreted allegorically the sweep of the story of creation, but the account of the Noachian flood, in contrast, is precise with measurements, including the dimensions of the ark and the duration of the flood.

On 7 February, 1973, John D. Morris, field director of the Creation Research Institute's Ararat Expedition spoke in Pinole, California, and showed slides of the search for the remains of Noah's ark. His organization is currently taking legal action to challenge the teaching of evolution. Its speakers assert that isotopic dating is erroneous, that evolutionary theory contravenes the second law of thermodynamics and that the fossil record shows an absence of "transitional forms", and is based on bones of animals that were drowned in the Noachian flood.

The Creation Research Society has demanded that, in school textbooks "both the theory of special creation and the theory of evolution are fully and fairly treated". We should therefore examine the details of the flood as explicitly set forth in Genesis 6-8. Genesis 6 specifies the dimensions of the three-story ark as having a volume of about 43,800 cubic metres (one cubit = 0.46 metre). Noah and his family, totalling eight, cared for all living terrestrial animal species for one year and ten days in the ark. This included gathering and loading the necessary food supply.

During the flood, the mountains were covered with water* "and every living
THOMAS H. JUKES

substance was destroyed which was upon the face of the ground . . . and Noah only remained alive, and they that were with him in the ark, and the waters prevailed on the earth 150 days".

The care of all living terrestrial species of animals would include the maintenance of an insectary containing about a million species, many of which are obligate predators or parasites upon others, and some upon vertebrates, an aviary with 25,000 species of birds and an animal colony containing, in addition to 2,500 species of amphibians and 6,000 species of reptiles, 15,000 pairs of mammals. The volume of the ark provided an average of less than 1 cubic metre for a pair of vertebrates plus their food supply. The mechanics of the "disposal problem" are not mentioned in any discussion I have seen. Another unmentioned problem was that of colonizing and preserving a culture collection of tens of thousands of species of bacteria and protozoa, including specialized parasites, before the existence of the microscope. Early explanations of such microbiology relied on the theory of spontaneous generation that was later ruled out by Pasteur's discoveries, and in any case is excluded by the Statement of Belief. The botanical problem is apparent, but is usually not mentioned.

If rain fell to a depth of 10,000 ft (a conservative estimate, insufficient to cover the mountains; actually "all the high hills that were under the whole heaven were covered" and Mt Ararat is 17,000 feet high), the volume of precipitation would have been 393,000,000 cubic miles, which is 1.4 times that of all the water presently on the earth. This rainfall occurred in 960 hours, at a daily rate of 104 ft. Its "drying up" took 167 days. Where did the water go? If it had rapidly entered the interior of the Earth, one would have expected numerous Krakatoa-like explosions. If it had escaped into outer space, why was not all the hydrosphere simultaneously dissipated?

NEWS AND VIEWS

Peptide pathology . . . of mice and men

from T. M. Jessell and J. S. Kelly

ANY examination of the significance of brain peptides in neuroendocrinology and neurology is assured of variety and diversity since more than 20 different peptide species have now been identified within the CNS (Hökfelt *et al. Nature* **284**, 515; 1980). Inevitably it is a little difficult to take an overall view in so novel a field. One objective of a recent meeting* was to explore, in particular, the clinical implications of recent research into neuropeptide function.

Encouraged by earlier work showing Parkinson's disease and Huntington's chorea to be associated with changes in transmitter levels, a number of laboratories have begun to map the distribution of neuropeptides in human tissue. It is, however, becoming clear from animal studies that the distribution of peptides in the brain is not necessarily the same as that of peptide receptors. For instance, the enkephalin concentration in the rat globus pallidus is extremely high, while the density of opiate receptors is only moderate. Similarly, bovine cerebellum is rich in angiotensin binding sites, but apparently devoid of angiotensin. Mapping the distribution of peptide receptors in human tissue may, then, provide clues to potential sites of peptide action that are not revealed by examining the distribution of the peptide itself.

A method applicable to human tissue was described by Pert and Herkenham (N.I.M.H. Bethesda) for opioid peptide receptors. The visualization of these receptors was achieved by labelling unfixed, slide-mounted sections of the brain, *in vitro,* with an opiate antagonist, ^{3}H-naloxone, fixing the label by lyophilization and exposure to hot paraformaldehyde vapours, followed by traditional autoradiographic processing. A similar method, developed by Young and Kuhar (*Nature* **280**, 393; 1979) has already been used to locate benzodiazepine receptors (for which one of the endogenous ligands may well be a peptide) within human cerebral and cerebellar cortex. It may, then, soon be possible to determine the precise distribution of peptide receptors within the normal and diseased human brain.

Some indication of the consequences of abnormalities in central peptide receptor

function might be obtained by studying similar disturbances in the periphery. J. Flier (Beth Israel Hospital, Boston) summarized evidence that a variety of disease states in man are produced by autoantibodies directed against cell membrane receptors. There is now substantial evidence that autoantibodies to the nicotinic acetylcholine receptor play a role in the aetiology of myasthenia gravis (Patrick *et al. Proc. natn. Acad. Sci. U.S.A.* **70**, 334; 1973, Almon *et al. Science* **189**, 55; 1974). More recently, Venter *et al. (Science* **207**, 1361; 1980) have reported the presence of autoantibodies to $ß_2$-adrenergic receptors in patients suffering from allergic rhinitis and asthma. Autoantibodies against peptide hormone receptors have also been found. The sera of some patients with Graves' disease contain two classes of thyroid stimulating immunoglobulins (Smith & Hall *Lancet* **ii**, 427; 1974; Manley *et al. J. Endocrinol.* **61**, 437; 1974). These immunoglobulins inhibit the binding of TSH to thyroid membranes and also stimulate thyroid adenylate cyclase activity leading to a clinical state of hormone excess. Similarly, the binding of insulin to its receptor is inhibited by circulating anti-insulin receptor antibodies in some obese patients with insulin resistance and numerous diabetic symptoms (Flier *et al. Science* **190**, 63; 1975). Almost exactly the same syndrome can be found in the genetically obese (NZO) mouse (Harrison & Itin *Nature* **279**, 334; 1979) which also has circulating autoantibodies that inhibit insulin receptor binding. Other inbred strains of laboratory animals may then provide models for as yet unreported disturbances in human peptide-receptor interactions. Could the low levels of opiate receptor binding and opiate resistance exhibited by the CXBK mouse (Baran *et al. Life Sci.* **17**, 633; 1975; Peets & Pomeranz *Nature* **273**, 675; 1978) for instance, be due to circulating antibodies to the opiate receptor? With so many peptide receptors to choose from, further examples of abnormalities in receptor function seem certain.

Of course, in the short term, it is more impressive when a single injection of a peptide produces a dramatic amelioration of symptoms. Sobue *et al.* (*Lancet* **i**, 418; 1980) have reported that a single, intravenous injection of thyrotropin releasing hormone (TRH) can bring about an immediate improvement in the major symptomatology of spino-cerebellar

degeneration. How TRH reduces body sway and nystagmus is unclear. Sobue suggests it may be related to the TRH-mediated improvement in abnormal noradrenaline metabolism in the cerebellum and brainstem seen in the mutant 'Rolling Mouse Nagoya'.

Another, more generally applicable therapeutic advance that may follow better understanding of the role of neuropeptides was reported by Holaday and Faden, (Walter Reed Medical Center, Washington D.C.) who found that a single, intravenous injection of the opiate antagonist naloxone could protect rats from otherwise lethal hypotension. The protective effects of naloxone are accompanied by an early restoration of blood pressure and appear to be equally effective in endotoxic, hypovolaemic and neurogenic shock (*Brain Research* **189**, 295; 1980). That the release of endorphins may be involved in the pathogenesis of shock is supported by Rossier *et al.* (*Nature* **270**, 618; 1977; *Science* **197**; 1368; 1979) who showed that ß-endorphin and ACTH are secreted concommitantly in response to stress. Since the stress-induced release of ß-endorphin has been confirmed in man, it is significant that ß-endorphin release is also induced in animals by the injection of morphine (Rossier *et al. Proc. natn. Acad. Sci. U.S.A.* **77**, 666; 1980). Morphine also inhibits the secretion of neurohypophyseal hormones (Clarke *et al. Nature* **282**, 746; 1979; Iversen *et al. Nature* **284**, 350; 1980) that may be involved in homeostatic responses to stress. Although these results may not support the introduction of naloxone in the treatment of the hypotensive, respiratory and hypothermic consequences of shock, they certainly draw attention to the possible adverse consequences of the use of opiates in patients bordering on shock.

Another attractive possibility for peptide therapy could be in the treatment of obesity. Although the precise role played by gastrointestinal peptides in the control of food intake is still far from clear, the release of cholecystokinin (CCK) or a shorter C-terminal fragment, such as CCK-8, may play a peripheral or central role in satiety (Gibbs *et al. Nature* **245**, 232; 1973; Straus & Yalow *Science* **203**, 68; 1979). Smith (Cornell University) reported that the suppression of food intake is

T.M. Jessell and J.S. Kelly are at St George's Hospital Medical School, London.

produced only by CCK and bombesin (Gibbs *et al. Nature* **282**, 208; 1979) and that the effects of CCK on satiety are decreased by gastric vagotomy (Smith *et al. Soc. Neurosci. Abstr.* **5**, 224; 1979). The central perception of satiety is, therefore, probably mediated through the vagus, rather than through circulating peptides passing the blood-brain barrier.

It seems clear that, with almost 30 neuropeptides and 300 diseases (Pliny; *Natural History* 7, Chapter 11, AD77) any summary of their relationship is premature. For the future direction of clinical research into neuropeptides, one need, as usual, go no further than to consult Robert Burton's treatise (*Anatomy of Melancholy*, Oxford, 1621) on diseases of the mind "that pertain to the substance of the brain itself, in which are conceived frenzy, lethargy, melancholy, madness, weak memory, coma and sleeplessness". □

Did Flamsteed see the Cassiopeia A supernova?

from David W. Hughes

CASSIOPEIA A is the brightest radio source in the sky and has been identified optically with a rapidly expanding emission nebulosity. Astronomers soon realised that Cassiopeia A was a supernova remnant and immediately started to question whether the supernova had been seen from Earth. Unfortunately there are snags. Firstly the source appears from Earth to be in the Milky Way. Calculations also show that it is 2,800 pc away (about a third the distance between us and the nucleus of our galaxy). So absorption along the path between the supernova and Earth will be considerable. Secondly an analysis of the rate of expansion of the nebulosity shows that the supernova would have been seen from Earth in about AD 1667 ± 8, assuming, of course, that it was visible at all.

Supernovae as a rule are difficult to overlook. The currently accepted production rate in our Galaxy is around two or three per century. They have a maximum brightness equivalent to an absolute magnitude of about −15. Without absorption the Cassiopeia supernova would have had, for a time, an apparent magnitude of about −3, similar to that of Jupiter or Venus. With absorption van den Bergh and Dodd (*Astrophys. J.* **162**, 485; 1970) suggested that a magnitude of +2 is more realistic. Even so, some astronomers have used the lack of a seventeenth century observation as a means of relegating Cassiopeia A to a class of abnormal supernovae. Maybe this is not necessary.

One of those interesting anomalies in science has occurred in which people have not only had similar ideas but have also published papers on the subject in the same month. William B. Ashworth Jr of the University of Missouri and Karl W. Kamper of the David Dunlap Observatory have both questioned whether Flamsteed recorded the supernova. Their papers appear respectively in the February editions of the *Journal of the History of Astronomy* (**11**, 1; 1980) and *The Observatory* (**100**, 3; 1980). The third worker, Peter Broughton, unknown to both Kamper and Ashworth recently read a paper on the subject to the Royal Astronomical Society of Canada.

John Flamsteed, the first Astronomer Royal, was actively cataloguing the sky during the period when the supernova could have been seen. Did he see it? Well Flamsteed recorded a star of sixth magnitude known as 3 Cassiopeia, close to the position of Cas A and there is no naked eye star visible in that position today. Certain possibilities arise. Flamsteed's catalogue appeared posthumously in 1725 under the title of *Historia coelestis Britannica.* unfortunately it contained numerous errors of observation, transcription, computation and publication. Francis Baily detected and corrected the great majority of these but the case of 3 Cas left him perplexed. He could not discover when Flamsteed had observed the star or how he could have seen a star which is no longer present. Baily concluded that the affair was 'singular'.

Caroline Herschel resolved the problem by stating that Flamsteed's 3 Cas was actually a faint 5th magnitude variable star AR Cas and that Flamsteed had made an error in calculating its position. Baily, however, found that Flamsteed has seen AR Cas as well as 3 Cas and rejected Herschel's solution.

William Ashworth investigated why Cas A has not been identified with 3 Cas before. He concludes that there were two main reasons. 3 Cas hasn't appeared in any star catalogue for more than 140 years, people believing it to be a mistake. Also, even if you went back to Flamsteed's catalogue, the reader would have been deterred by the statement that the original observations from which the position of 3 Cas was reduced cannot be found. Ashworth and Kramer, however, did find them, among the early sextant observations printed in Halley's 1712 edition. Flamsteed had apparently recorded the distance of 3 Cas from two brighter stars, Beta Pegasi and Beta Persei. The observations were made on 16 August 1680.

At this point the two authors start to diverge. Ashworth notes that the positions of Cas A and 3 Cas differ by 12.1′ in right ascension and 8.6′ in declination. Considering that Flamsteed insufficiently accounted for atmospheric refraction in one of his determining stars and that the sextant observations suffered from errors Ashworth concludes that the actual

Flamsteed's 3 Cassiopeia lies at the tip of the sceptre of Cepheé. From Atlas Céleste de Flamstéed, L'Académie Royale des Sciences, Paris, 1776; by courtesy of the Royal Astronomical Society, Burlington House, London.
David W. Hughes is in the Department of Physics, University of Sheffield.

observing error was approximately 6′. Flamsteed regularly made errors of 1′ and discrepancies of 4′ are not infrequent so an error of 6′ is not unprecedented. To quote Ashworth "It seems almost certain that John Flamsteed did indeed observe the Cassiopeia A supernova in 1680". According to David H. Clark and F. Richard Stephenson (*The Historical Supernovae*, Pergamon) there have been four certain, two probable and two possible historical observations of supernovae in the Galaxy. Flamsteed's would be the ninth and latest.

Kamper is much more cautious. He suggests that the two sextant observations recorded by Flamsteed on 16 August 1680 were not of one star but of two different ones which still exist and are close to Cas A. The arc from Beta Pegasi agrees with the position of the 5th magnitude variable AR Cas to within an error of 32″. The arc from Beta Persei agrees with the 7th magnitude star BD + 56° 2999 to within an error of 64″. Both these errors are comparable with the errors of other arcs measured on that night. Kamper concludes that he can make no case for Flamsteed's supernova.

But does the story end here. Instead of asking Flamsteed to make a 6′ error in a sextant measurement we are now asking him to overlook the fact that the star he was observing that night had mysteriously dropped in brightness by two magnitudes. I think the least we can say is that the question is still open. □

An X-ray image of Kepler's supernova remnant obtained with the High Resolution Imager aboard the Einstein Observatory.

X-ray images of supernova remnants

from David J. Helfand

THAT the Crab Nebula is object number 1 in the eighteenth century Messier Catalogue of diffuse celestial objects testifies to the long-standing importance of optical imaging in the study of supernova remnants (SNR). Excluding the Crab, however, the optical radiation from the debris of these massive stellar explosions is primarily limited to the relatively dense cool regions in the swept up interstellar matter or, in the case of the youngest remnant Cas A, to knots of ejected material. With the advent of interferometers, SNR were among the first objects imaged by radio astronomers. The radio emission is thought to be more closely associated with the expanding shock wave from the explosion, arising as it does from the acceleration of high energy particles in regions of turbulent gas and compressed magnetic fields. However, the total flux emitted in the radio regime is but a tiny fraction of the overall energy budget of the remnant.

It is the X-ray emission that traces out the boundary of the expanding shock and dominates the radiative energy losses of the remnant for the first 20,000 yr. It is X-ray emission that can provide information on the possible collapsed remnants of the explosion (neutron stars or black holes), and it is the X-ray emission which allows us to use the SN shock to probe the structure of the interstellar medium (ISM). As a result of this rich potential, many rocket payloads and much observing time on satellite modulation colimator experiments have been dedicated over the past decade to producing X-ray images of large, nearby SNR such as Vela, Puppis A, the Cygnus Loop, and, through lunar occultation, the Crab Nebula. The best spatial resolution obtained was typically a few arc minutes. Recently published results of such experiments are a map of the northeast region of the Cygnus Loop which shows evidence for X-ray emission outside the boundary of the optical filaments (Tuohy

et al. Astrophys. J. Lett. **L101**; 1979) and a HEAO-1 modulation collimator image of Tycho's remnant indicating a roughly spherical shell with enhanced emission from the western limb (Fabbiano *et al. Astrophys. J.* **235**, 163; 1980).

As in the rest of X-ray astronomy, however, the launch of the Einstein Observatory a year and a half ago has provided a quantum leap in our abilities to produce X-ray images of SNR (*Nature* **279**, 371; 1979). With vastly increased sensitivity and arc second spatial resolution, these new pictures are surpassing our expectations of what is to be learned in each of the areas noted above: SNR dynamics and evolution, the physics of collapsed remnants, and the structure of the ISM. The only picture published to date is that of Cas A (Murray *et al. Astrophys. J.* **234**, 169; 1979). It shows a generally spherical shell outlining the blast wave's progress studded with bright knots of emission, some associated with the fast moving ejecta and others overlying optical filaments linked to the interstellar or circumstellar material heated by the passage of the shock. No central point source, expected if a hot neutron star had been a product of the explosion, is present.

Images of nearly 50 other remnants have already been collected and preliminary results for many of these were discussed in contributed talks and an invited review at the recent meeting of the High Energy Astrophysics Division of the AAS in Cambridge, Massachusetts. Most remnants of the historical supernovae show well-defined, circular, limb-brightened shells, although, large brightness variations around the rim are a common feature. The enhanced emission near the shock front begins to fade as the remnant ages: several remnants thought to be more than 10–20,000 years old no longer

David J. Helfand is in the Department of Astronomy, Columbia University, New York.

show a clearly defined boundary between remnant and ISM, and only an amorphous volume of cooling gas belies the presence of the recent explosion. The detection of more than 20 remnants in the Large Magellanic Cloud (where distances are determined to better than 10%), offers an excellent sample of objects for use in the study of remnant evolution.

Another type of X-ray morphology is exemplified by the distinct class of remnants for which the Crab is the archetype. Emitting synchrotron rather than thermal photons and powered by the rapidly spinning central pulsar rather than by an expanding shock, the Crab-like remnants show X-ray surface brightness distributions which are sharply peaked toward the central source. Several prospective members of this class, first suggested by radio studies, are being examined with Einstein, and at least two have already been detected, although a search for X-ray pulsations from them has not yet been effected.

One of the questions to be addressed with these high resolution images is that of the prevalence of neutron stars in SNR (Helfand *et al. Nature* **283**, 337; 1980). Theoretical work prior to last year led to the expectation that a neutron star, formed at a temperature of 10^{11} K, would remain hot (> few million degrees) long enough to be observed in any of the remnants less than a few thousand years old. In fact, point sources have been found in only three objects: the Crab and Vela remnants which were already known to contain radio pulsars, and the young southern remnant RCW 103 (Garmire & Tuohy *BAAS* **11**, 791; 1980). In the case of the Crab, most of the emission is pulsed (and, presumably, nonthermal), although a recent result indicates that there may be an unpulsed component, (< 1% of the total) which represents thermal emission from the stellar surface at a temperature of 2×10^6 K (Harnden *et al. BAAS* **11**, 789; 1980). In Vela, an arc second resolution image shows that there is an extended X-ray nebula surrounding the pulsar (a scaled down version of the Crab Nebula), making separation of the surface neutron star radiation difficult (Harnden *et al. BAAS* **11**, 424; 1979). For RCW 103, the flux from the weak point source at the remnant centre also yields a temperature of $\sim 2 \times 10^6$ K for

a 15 km neutron star. Limits for most of the other young remnants lie in the range of 0.5 — 2 × 10⁶ K and, while a burst of activity on the part of theorists has pushed the predictions to lower values, our current understanding of neutron star physics will probably not admit the possibility of cooling a remnant in SN1006 to half a million degrees in less than a thousand years. Thus, we must conclude either that the standard cooling theory is incorrect (presenting an important fundamental lesson in the physics of matter at supranuclear densities), or, that the majority of SN do not leave pulsars behind (driving the discrepancy between the pulsar birthrate and the galactic SN rate into such violent disagreement that a new method of producing neutron stars need be found).

Yet another important facet of the X-ray SNR images is the information they can provide on the nature of the ISM. Our ideas about the distribution of diffuse matter in the galaxy have changed dramatically in the last five years. The once rather homogeneous picture has been supplanted by observations which show ranges in temperature from 10^1 to 10^6 K and ranges

in density of from 10^8 to 10^{-3} cm^{-3}. While circularly symmetric expansion shells and correlations of X-ray enhancements with optical filaments recall the largely (> 90%) diffuse medium and evaporating cloudlets suggested by McKee and Ostriker (*Astrophys. J.* **218**, 148; 1977), the large scale brightness changes around the limb of many remnants suggest a large scale (~ 10pc) structure to the ISM reminiscent of the interstellar tunnels of Cox and Smith (*Astrophys. J. Lett.* **189**, L105; 1974). Comparison of the morphology of the LMC remnants with their local galactic environment and the detailed correlation of X-ray, optical, and radio maps with ~ 10^3 AU spatial resolution for nearby remnants such as the Cygnus Loop will clearly have a major impact on this problem in the future.

Detailed work in many of the areas outlined has only just begun. The preliminary results assure us, however, that from the structure and evolution of the remnants themselves, to the physics of neutron stars and the study of the energy balance and structure of the ISM, the contribution to be made by X-ray imaging of SNR is large indeed. □

are shown in the lower part of Fig. 1. In this case the residues of the projectile and the target remain distinct and they are kicked apart by the highly compressed head shock zone. The uranium nucleus moves slowly at right angles to the initial projectile direction and its large deformation and angular momentum makes it likely that it will fission, while the projectile is deflected through about 30°.

Figure 2 shows how these two types of collision are distingushed by the characteristic dependence of the energy and angular distributions of the fragments on the impact parameter. As the impact parameter increases, the angular distributions broaden and the peak angle for the projectile fragments moves to smaller angles. The high-energy tail of the spectra increases with the impact parameter due to the deflected projectile residue and to the matter from the exploding headshock wave. For large impact parameters there are two distinct contributions to the matter distribution, one from the bounced-off projectile-like fragments at large transverse and forward momenta and the other from the residue of the target at low parallel and perpendicular momenta.

Many of these features of energetic nuclear collisions have been found experimentally. Studies of neon-gold interactions at Berkeley by Meyer and collaborators show heavy-target residues moving at right angles to the incident beam in coincidence with correlated jets of fast light particles in the opposite azimuthal direction, just as in the lower part of Fig.

Hydrodynamical analysis of energetic nuclear collisions

from Peter Hodgson

WHEN two nuclei collide at energies of several hundred MeV. per nucleon all the nucleons are involved in a violent interaction that is too complicated to analyse in terms of their individual motions. Instead a good overall understanding of the interaction can be obtained by using the methods of classical hydrodynamics.

A calculation of this type has recently been made by Stöcker, Maruhn and Greiner (*Phys. Rev. Lett.* **44**, 725; 1980) and the results show how the character of the interaction depends on the classical impact parameter.

They made their calculations for the collisions of 400MeV. per nucleon neon nuclei with uranium nuclei. The nuclei were treated as fluid systems described by the Euler equations, and these were integrated numerically in three dimensions. This automatically ensures the conservation of particle number, momentum and energy. The nuclear characteristics were included through the equation of state, which gives the dependence of the internal energy and pressure on the local density and temperature. The internal energy comprises the compression energy and the thermal energy. For the compression energy they used a parabolic expansion around the ground state density with a

Peter Hodgson is in the Department of Nuclear Physics, University of Oxford.

compression constant of 200MeV. and for the thermal energy a Fermi gas expression. The Coulomb and Yukawa potentials were included, thus giving a realistic account of the binding and surface energies of the nuclei.

These calculations give the time evolution of the collision process, and they were continued until the nucleons were so far apart that they could no longer be considered to be in thermal contact. Calculations were made for various values of the impact parameter b, the distance of closest approach in the absence of interactions, and some of the results are shown in Fig. 1. The upper picture shows the density and temperature contours and the velocity field (arrows) in the scattering plane at a late stage of a head-on collision ($b = 0$). It is notable that a strongly compressed, highly excited head shock is formed, and this pushes matter sideways giving a strong sideward compression wave. The particle velocities are everywhere small and no projectile-like fragments are observed, showing that all the forward momentum of the projectile has been transferred to the combined system. The angular distribution of the emitted fragments is given in Fig. 2, and shows a sideways peak at the Mach shock angle of about 70°. Most of the particles in the peak have quite small kinetic energies around 20 MeV.

The results of calculations for an intermediate impact parameter ($b = 6$ fm)

Figure 1 Nuclear density and temperature contours and velocity field (arrows) in the scattering flow at a late stage of the collision of a 400MeV. per nucleon neon nucleus with uranium. The upper picture is for a head-on collision and the lower for an impact parameter of 6 fm.

Figure 2 Variation with impact parameter of (a) the angular distribution (inset: position of maximum) and (b) the energy spectrum of the reaction products.

1. Studies of nearly central collisions of neon with uranium at Darmstadt by Stock gave a broad distribution peaked around 90° for the low-energy particles, and this becomes narrower and shifts to forward angles with increasing kinetic energy, in qualitative agreement with the hydrodynamical calculations.

These calculations show that many of the features of energetic collisions between nuclei can be understood using classical hydrodynamical concepts. Such collisions subject nuclear matter to very high pressures, and thus provide a way of testing the nuclear equation of state that is employed in the calculations. An additional possibility is the discovery of abnormal super-dense states of matter from irregularities in the excitation function of the Mach shock-wave angle and in other measurable quantities like the pion production rate and the nuclear temperature. □

Bio-Energy '80*

from D. O. Hall

WHEN over 1800 people and large official delegations from Brazil, China, France, Sweden and the US get together for discussions and to display equipment for biomass-for-energy systems then something serious must be happening in the field — such a meeting was inconceivable even two years ago. That something, of course, is the belated realization that the world's oil production has already peaked (not for technical reasons) and that future oil price increases

will be maintained above the inflation rate. In addition it is recognized that biomass already supplies about 15% of the world's energy but because this use occurs mainly in the rural areas of the developing world it has not been given due attention. Even in the developed world the US currently derives 2% and Sweden 10% of its energy from biomass.

The Bio-Energy Council of Washington, D.C. — a foundation and subscription funded organization — has only been established for some three years and has already made a significant impact in the biomass-for-energy field. Their main aim is to serve as an international information centre and to this end they have already published the third edition of the *Bioenergy Directory 1980* — it contains over 650 one-page summaries of bio-energy activities in 34 countries and also abstracts 250 additional reports from the 1979 Directory.

The Congress was so large that only a partial view can be given. The 'hottest' topic was undoubtedly the alcohol programmes of Brazil and the US. Brazil leads the world as it started its programme in 1975 and now spends about $700m a year. About 4 billion litres of ethanol will be produced in 1980 and about 10 billion litres in 1985. The alcohol is blended to 20% in petrol but a quarter of a million cars will be produced this year alone to run on 100% alcohol. The Government is controlling the rate of use of alcohol to try to prevent shortages or surpluses.

The main source of alcohol is sugar cane but cassava, sweet sorghum and babussu palm are being rapidly developed as crops with wider land potential and less stringent agronomic requirements. Brazilian companies can now sell turn-key plants to the rest of the world. A Brazilian speaker made it clear that the decision to implement the programme was a political one and that economic and technical factors played secondary roles. The discussion of energy ratios was, according to him, totally irrelevant. Energy independence and foreign currency savings were the key factors. This point was well taken by the US Congressmen from the Iowa cornbelt who is one of those pushing the US gasohol programme in Washington. The Americans blend alcohol to 10% in gasoline and it is now being sold in thousands of stations in the US. It has received tax credits from Federal and State governments and is very popular with the public who perceive it as one way of 'helping America'. Current biological alcohol production in the US is about 80m gallons per year; it is hoped to expand this to 500m gallons per year within 2 or 3 years by massive federal aid — about $1 billion per year for up to 10 years.

D.O. Hall is a Professor of Biology of King's College, London and past-chairman of the UK Section of the International Solar Energy Society.

Surplus corn is the primary source of feedstock now, but other grains, sweet sorghum, sugarbeet, sugar cane and other crops are being examined. Small-scale ethanol producing facilities on farms are being rapidly implemented and encouraged. Local self-sufficiency is the prime aim. Surplus sugar production from sugarbeet in Europe and from sugar cane in tropical countries was also widely discussed as a potential source of alcohol.

Direct combustion of wood, residues from agriculture and forestry, and wastes from cities and industry is already commercially viable in many parts of the States — especially in the north east where energy costs are high and organic matter is abundant. This use of biomass and the construction of biogas generators seemed the next most popular topics of discussion. The Chinese delegation described how they have constructed 7 million biogas digestors over the past few years and are currently building them at the rate of 1 million a year. Attention is also being given to the production of methanol from woody material — especially since such technology is compatible with coal-based systems. This was certainly stressed by the Europeans and Canadians — and would find echoes in Australia and Brazil.

There seems little doubt that biomass-for-energy systems are here to stay and their implementation must certainly be encouraged. Like any energy systems there are disadvantages in using biomass, e.g. land use competition, requirements for fertilizer and water, soil erosion problems, uncertain costs at this early stage, lack of infrastructure, and so on. The one most controversial topic right now is that of food versus fuel — should we divert plant material to fuel and away from its use as a food, or is there a rational way of providing both, e.g. by feeding corn to make ethanol and use the stillage as cattle feed. These discussions will inevitably intensify. In developing countries decisions on reforestation and rehabilitation of semi-arid regions must be made quickly if energy (mostly in the form of woodfuel and residues) is to be available on a continous basis.

To those of us who have been advocating careful, continued and increasing use of biomass as a source of fuel this Congress and Exhibition was a dream come true. Even two or three years ago such an event may have been fortunate to attract a few hundred dedicated persons. Now the field is recognized to be of worldwide importance and will probably continue to be so as long as the 'energy problem' continues. This is likely to be for at least the next 15 to 20 years as the world pays the price of decisions made in the 1950s and 1960s which locked us in to an oil economy. The decision cannot be reversed quickly and we are belatedly realizing this fact. Biomass will be only one component in a future energy mix but it can provide liquid, gaseous or solid fuels as required. □

Biotechnology and the production of proteins

from A.J. MacLeod

THE idea of using recombinant DNA techniques to construct bacterial strains capable of synthesizing therapeutic proteins is currently being widely promoted. It is not, though, the only possibility for large scale production of proteins and the advantages and disadvantages of different methods need to be considered. Particularly for proteins intended for therapeutic use there are severe constraints on the precise nature and purity of the products.

Bacterial methods would seem to have the advantage of almost limitless production with recovery from a relatively simple mixture. However, apart from albumin, virtually all of the protein species in plasma are glycoproteins or lipoproteins. Modulation of the antigenicity or pharmacokinetics of the proteins is likely to be important *in vivo* and the ability of bacteria to reproduce these features faithfully is doubtful. This problem may be reduced by *in vitro* modification (Marshall & Humphreys, *J. appl. biochem.* **1**, 88; 1979). As bacteria degrade abnormal proteins efficiently (Goldberg & St John *Ann. Rev. Biochem.* **45**, 747; 1976) it is probable that partial digestion of the product will occur with effects on biological activity, even if antigenic loci remain intact.

Should synthesis of significant quantities of biologically active protein be achieved in a bacterial system, its recovery will still present major difficulties. In systems where secretion of human proteins, with or without a bacterial protein carrier, has been attempted, secretion has occurred into the periplasmic layer and the products have not successfully passed into the culture supernatant. (Villa-Komaroff *et al. Proc. natn. Acad. Sci. U.S.A.* **75**, 3727; 1978. Fraser & Bruce *Proc. natn. Acad. Sci. U.S.A.* **75**, 5936; 1978). Protoplasts have to be prepared to release the proteins but this has the disadvantage of releasing a mass of other bacterial products and debris into the crude preparation. If the cells have to be lysed to release accumulated protein this problem will be much more severe. Even if secretion into the culture supernatant can be achieved bacterial products and debris will still be present as contaminants.

Bacterial proteins are intensely antigenic in mammals and cell debris is pyrogenic. Even trace levels of bacterial contamination repeatedly administered over a long period, as in the control of haemophillia or in cancer therapy, may be dangerous. Products from bacterial cultures will have to approach absolute

A.J. MacLeod is the Protein Fractionation Centre, Scottish National Blood Transfusion Service, Edinburgh.

purity. However, as greater purity is sought with large-volume processes costs rise exponentially and consequently the processing cost may offset the initial production cost advantage of bacterial systems. A particular difficulty in this case, as opposed to the production of antibiotics or viral vaccines, is that some of the impurities will be very similar, chemically and physically, to the product.

Rather than using bacterial systems for human protein production it might be better to manipulate human cells so that they can be cultured more easily and be more productive. The plasminogen activator urokinase produced by normal human kidney cells *in vitro* is already available for clinical use (Lewis *Thrombos. Haemostas.* **42**; 895; 1979). Transformation of mammalian cells with genes from prokaryotes and eukaryotes has been demonstrated (Wigler *et al. Cell* **16**, 777; 1979). A more direct route to a satisfactory cell line might be to construct cell hybrids as has been done with leukocyte-lymphoblastoid hybridomas (Galfre *et al. Nature* **266**, 550; 1977). A step in this direction was the recent announcement by Widman *et al.* (*J. Cell. Phys.* **100**, 391; 1979) of the immortalization of a normal differentiated liver function in a hepatoma cell hybrid. The liver is the site of production of many of the plasma proteins. Systems capable of supporting very large-scale cultures of animal cells have been developed and are being introduced in association with established fermentation technology (*Eur. Soc. Anim. Cell Technol.* 3rd Meeting, *Develop. biol. Stand* **46**; 1980).

The advantages of human cell systems are that the products are likely to be correctly modified, they should be secreted into the medium, and antigenicity and pyrogenicity will be much reduced. Cell lines have the advantage that the cultures will not age as do normal cells and it may even be possible to construct lines that will grow and function in suspension. The disadvantages with cell lines include the incorporation of tumour cells that could release oncogenic material. However, methods of overcoming this problem have been suggested (Hillman *Advances Exp. Med. Bio.* **118**, 47; 1978).

The absolute homogeneity of the products from cloned systems may cause considerable complications in their use. Genetic polymorphism of plasma proteins resulting in multiple allelic forms is now well established with more than 20 variants of human albumin identified to date. Administration of such products over a prolonged period, if they do not match the recipients serum type, could induce the production of antibodies. Avoiding this could require production from several cell strains, each producing material of a

different serum protein-type. The plasma proteins currently available minimize this complication because they are prepared from pooled donation and thus contain a variety of serum protein types. Even so the development of antibodies to factor VIII in haemophiliacs receiving therapy can occur (Shapiro *Clinics in Haematology* **8**, 207; 1979).

Human protein has already been in use for some 30 years from products of the industrial fractionation of plasma from routine blood donations. Improvements in process control, fluid handling and separation techniques applied to the established cold-ethanol precipitation process have facilitated the design of a continuous, sequential precipitation process that yields defined fractions from large volumes of plasma. The products currently available include the albuminoid stable plasma protein solution, various immunoglobulin preparations and coagulation factor concentrates (Watt & Dickson *Proc. Int. Workshop on Technology for Protein Separation and Improvement of Blood Plasma Fractionation, U.S.D.H.E.W.* Publ. No. (NIH) 78 — 1422, 245; 1978). These products are widely used but their quality is affected by damage to the proteins during processing and by contamination. The latter include both exogenous material such as hepatitis B virus and bacterial pyrogens, and redundant plasma proteins which may be biologically active, provoking, for instance, thrombogenic or hypotensive side-effects. These problems can largely be attributed to the inherent difficulty of recovering a substantial proportion of a particular component from a milieu as complex as plasma.

An attractive possibility might be to exploit the well established techniques of plasma fractionation along with developments in human cell culture. Currently, substantial quantities of human protein pastes are produced as by-products of plasma fractionation. These byproducts consist largely of α and β globulins, and low molecular weight proteins and have already been shown to contain many of the specific components required for serum-free culture of animal cells *in vitro* (MacLeod & Drummond *Develop. Biol. Stand.* **46**, 17; 1980) The preparation of a nutrient culture medium for human cells based on human plasma proteins would avoid exposure of the cells to heterologous proteins which could subsequently contaminate the product (Bonin *et al. J. Biol. Stand.* **1**, 187; 1973). Thus it is possible to envisage a situation where human plasma would be collected and processed to yield albumin and possibly some immunoglobulins. The remainder would be processed to support the synthesis of a wide range of products by human cells *in vitro*, the whole constituting an integrated unit based on technology of which much is already well developed. □

Mapping radio sources with uncalibrated visibility data

A. C. S. Readhead, R. C. Walker, T. J. Pearson & M. H. Cohen

Owens Valley Radio Observatory, California Institute of Technology, Pasadena, California 91125

There are many situations in which it is possible to detect interference fringes, but with large systematic errors in amplitudes. A new method is described for mapping objects from such data. In principle this method is applicable to any system which can produce detectable fringes, and is not limited to radio frequencies.

IN very long baseline interferometry (VLBI) radio astronomers are faced with making maps from visibility data with large systematic phase and amplitude errors. At frequencies below 10 GHz it is usually possible to calibrate amplitudes to 5%, but the phases cannot be calibrated except in a few special cases. Jennison[1,2] showed that it is possible to derive a good observable from the observed phases by forming the algebraic sum of these phases around a closed loop of three, or more, baselines. Rogers *et al.*[3] called this the "closure phase", and used it to derive structure from VLBI observations.

Hybrid mapping, incorporating the use of the closure phase, has now become a standard method of producing maps from VLBI data[4-6]. A limitation of this method is that it relies on well calibrated amplitude data, which are difficult or impossible to obtain at high frequencies ($\geqslant 10$ GHz). Thus, few reliable continuum maps have yet been made at or above 23 GHz, although several telescopes now operate at this frequency.

Twiss *et al.*[7] showed that it is possible to derive a good observable from uncalibrated amplitudes by forming ratios of the amplitudes observed on four or more baselines. We shall refer to such amplitude ratios as 'closure amplitudes'. They considered the limited case in which there are two or more equal spacings, but we shall show that closure amplitudes can also be used in non-redundant situations, such as obtain in VLBI or at the Very Large Array (VLA) in New Mexico. We present examples which show that the closure amplitude is a good observable, with errors determined by the random noise at the individual telescopes. Most of the systematic amplitude errors due to a particular telescope cancel exactly. These include amplitude errors due to atmospheric absorption and emission, to telescope gain errors, and to receiver temperature and gain variations. If the object is much smaller than the primary beam width of the individual telescopes, the pointing errors also cancel.

We describe here an extension of the hybrid mapping procedure which uses the closure amplitudes instead of the observed amplitudes. We have conducted some blind tests which confirm that reliable maps can be made from the closure amplitude and phase.

The closure amplitude

The complex visibility function of a source of brightness distribution $I(\sigma)$ is

$$V(\mathbf{b}) = \int_{-\infty}^{\infty} d\sigma \, I(\sigma) \exp(2\pi i \mathbf{b} \cdot \sigma) \qquad (1)$$

(ref. 8). An interferometer composed of two telescopes p, q measures the complex correlation coefficient, ξ_{pq}, between the electric fields at the two antennas. The relationship between the observed ξ and V may be written

$$\xi_{pq} = K_{pq}(G_p G_q)^{1/2} \exp\{2\pi i (\psi_p - \psi_q)\} V(\mathbf{b}_{pq})$$

where $\mathbf{b}_{pq}$ is the vector separation of the telescopes in wavelengths; K_{pq} depends on the correlator; the constants G_p and G_q represent the effects of the gain of the telescopes and the absorption in the atmosphere; and ψ_p and ψ_q represent the phase errors associated with the two telescopes, including propagation effects, oscillator drifts, clock errors and errors due to uncertainties in the positions of the source and the telescopes. Thus errors introduced in propagation from the source to the telescope and from the telescope to the correlator are included in G and ψ, while errors introduced during or after correlation are included in K. In many interferometer systems the observed correlation coefficient also depends on the system temperature at each telescope. This effect can also be included in G.

If measurements of the visibility are made on a sufficient number of different baselines $\mathbf{b}$, the brightness distribution of the source can be reconstructed by Fourier inversion of equation (1). This is the principle of aperture synthesis. If the constants G_p, ψ_p and so on are subject to large uncertainties, however, this is not possible; but all is not lost if simultaneous observations are made with a network of four or more telescopes.

When observations are made with four telescopes p, q, r, s the closure visibility A_{pqrs} can be calculated:

$$A_{pqrs} = \frac{\xi_{pq}\xi_{rs}^*}{\xi_{pr}\xi_{qs}^*}$$

It can be seen that in this ratio the G and ψ factors cancel and

$$A_{pqrs} = \frac{V(\mathbf{b}_{pq})V^*(\mathbf{b}_{rs})}{V(\mathbf{b}_{pr})V^*(\mathbf{b}_{qs})}$$

is simply the corresponding ratio of the four complex visibility functions, assuming the factors K are all equal, which is the case if all the interferometer pairs are correlated in the same way. The closure amplitude is defined as the modulus of the closure visibility $|A_{pqrs}|$. The argument of the closure visibility is the closure phase defined around a quadrilateral.

Table 1 The fraction of visibility information in closure amplitudes and phases

No. of telescopes	No. of baselines	Fraction of amplitudes	Fraction of phases
3	3	0	0.33
4	6	0.33	0.50
5	10	0.50	0.60
7	21	0.67	0.71
10	45	0.78	0.80
15	105	0.86	0.87
20	190	0.89	0.90

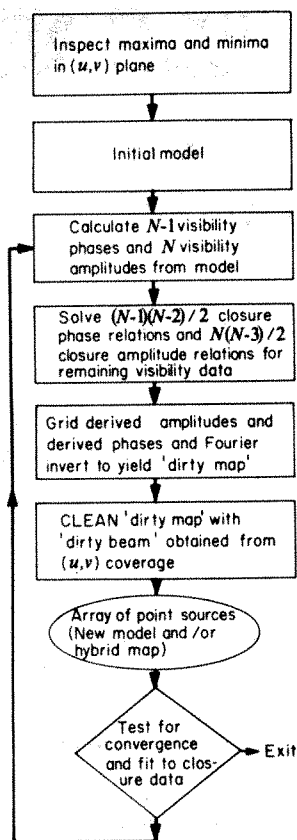

Fig. 1 Flow diagram of hybrid mapping procedure using closure phases and closure amplitudes.

If all six of the interferometer pairs formed by the four telescopes are available, three independent closure visibilities can be calculated: A_{pqrs}, A_{pqsr} and A_{psrq}. However, there are only two independent closure amplitudes.

For N telescopes there are $N(N-1)/2$ pairs, and there are N values of G at each instant. There are also N values of ψ, but the origin of the phase is arbitrary, and can be set to zero for one telescope. The values of ψ are then the phase errors relative to this telescope, and there are $N-1$ independent values. In an array with no redundant spacings the number of independent closure phases is thus $N(N-1)/2 - (N-1) = (N-1)(N-2)/2$, and the number of independent closure amplitudes is $N(N-1)/2 - N = N(N-3)/2$. In a non-redundant array, therefore, the fraction of the total visibility information in these two good observables is $(N-2)/N$ in closure phases, and $(N-3)/(N-1)$ in closure amplitudes. Table 1 shows these fractions for different numbers of telescopes, and demonstrates that the improvement achieved by adding an extra station is significant up to $N = 10$, by which stage nearly 80% of the visibility information is contained in the closure data.

This analysis assumes no redundancy. However, in a redundant array the number of free parameters is further restricted, and this can be an advantage in some situations. Rogers[9] has considered this point in the case of closure phases.

Observational test

Systematic errors due to a given telescope cancel exactly in the closure amplitude, but systematic errors can also arise if the K-factors are not equal for all the interferometer pairs. Such effects could be caused, for example, by a correlator bias. Table 2 shows an example of the observed closure amplitudes on a four telescope network, at 5,011 MHz on the BL-Lacertae object AO0235. AO0235 has long been used as a calibration source at this frequency on US baselines, and is thought to be slightly resolved on transcontinental baselines. Note that the closure amplitude $|\xi_{BH}\xi_{ON}^*/\xi_{BO}\xi_{HN}^*|$ is consistent with unity. This is expected for a

B, Bonn 100-m telescope, FRG; N, NRAO 41-m telescope, US; O, OVRO 40-m telescope, US; H, Hat Creek 26-m telescope, US. The maximum projected baseline lengths perpendicular to the line of sight to AO0235 are: BN—106, BO—137, NO—56, BH—135, NH—59 and OH—8, in units of $10^6 \lambda$. In forming the closure amplitudes we have taken the values of the raw correlation coefficients observed in 2-min coherent integrations, formed the closure amplitudes, and then averaged over 20 min. The errors are the s.e.m. for each 20 min interval.

source which is only slightly resolved, as the distance between Hat Creek and the Owens Valley is so small compared with other distances, thus $\gamma_{BH} \approx \gamma_{BO}$ and $\gamma_{NH} \approx \gamma_{NO}$ (γ_{BH} is the amplitude of the visibility, $|V(\mathbf{b}_{BH})|$). This demonstrates that, to within the level of accuracy of these measurements ($\leqslant 2\%$) the systematic amplitude errors cancel, as expected. This is a good test of the interferometer network. The other two closure amplitudes are the same, within the errors, in each interval, and they show the same trend over this 3-h period—they both increase from 1.09 at 05 h 13 min to 1.32 at 08 h 11 min. This is because $\gamma_{BO} \approx \gamma_{BH}$ and $\gamma_{NO} \approx \gamma_{NH}$ for this object. Note also that these closure amplitudes are always above unity. This is to be expected because γ_{BO} and γ_{BH} are less than γ_{BN}, and γ_{NO} and γ_{NH} are less than γ_{OH}.

Hybrid mapping with the closure amplitude

Although the closure amplitude is a good observable, it is difficult to interpret because it involves visibility amplitudes at four different points in the (u, v) plane. A similar problem arises with the closure phase, involving three points in the (u, v) plane. This problem is overcome in the hybrid mapping procedure[5], by assuming a model brightness distribution, and using the model
Fig. 2 Test 1: *a*, the test object, convolved with the gaussian beam with FWHM shown by the hatched ellipse. Contour levels, 5, 15, 25, ...95% of peak intensity. The object is assumed to be at $\delta = 50°$. *b*, Hybrid map derived from closure amplitudes and phases. The raw data have been badly corrupted by systematic and random errors (see text). There are no negative contours $\leqslant -5\%$.

Fig.3 As for Fig, but for Test 2. Contour levels, 5, 15, 25....95% of peak intensity. There are no negative contours ≤—%. Component A has 10 contours to the peak.
phases on $(N-1)$ baselines and the closure phase relationships to solve for the phases on the remaining baselines. This enables us to make a map, which is then used as the model, and we iterate until a stable solution is reached. To make use of the closure amplitudes we have extended this procedure. We now use the model to set the amplitudes on N baselines and the phases on $N-1$ baselines, and solve all the closure relations, both amplitude and phase, to obtain the amplitudes and phases on the remaining baselines. A flow diagram of the procedure is given in Fig. 1.

If there are data missing on some baselines, the maximum number of closure amplitudes which might have to be searched for a solution is $3\binom{N}{4}$, which rises rapidly with N, but this does not pose a serious computing problem. The computer time required for the phase and amplitude calculations is less than that required to Fourier-transform the data and clean the resulting map even for a 27 station array such as the VLA.

There are other ways to use the closure amplitudes. For example, a procedure is being developed at NRAO by Schwab[10], which attempts to ascribe phase and amplitude errors to specific telescopes by comparing the observed quantities with quantities derived from a model of the source. An iterative procedure is then used to obtain a self-consistent solution. This self-consistent solution is simply that in which the closure relations are satisfied, and thus this procedure is equivalent to hybrid mapping.

In the full hybrid mapping procedure, using closure amplitudes as well as closure phases, the absolute flux density and the position of the source are lost. However, the flux density can be recovered if a single baseline can be calibrated. The position of the source is more difficult to recover, and requires a properly phase stable interferometer to provide good phase information on a single baseline.

Blind tests

We have tested the usefulness of the closure amplitudes by performing blind tests in which sources were invented by one of us, and solved by another. In each case the solution was not revealed until a final map had been decided on, and a short description of the source had been written.

To simulate the real situation, gaussian noise was added vectorially to the simulated data to produce errors in both amplitude and phase. In addition, random factors were applied to the amplitudes to simulate the effects of bad weather, mispointing of antennas and gain errors at each telescope. The main effect of these errors was to decrease the amplitudes, as happens in practice. The random gain variations altered the amplitudes by factors of up to 3, making it impossible to map the sources by conventional means. The only effect on the closure amplitudes is to increase the noise. This increase is substantial in cases where the amplitude is severely reduced. The mapper was given the corrupted amplitude data, and the closure amplitude and closure phase data.

The first two tests simulated observations at 23 GHz with a network of six telescopes at Bonn, West Germany; Haystack,

Massachusetts; Green Bank, West Virginia; Algonquin, Ontario; the VLA, and Owens Valley Radio Observatory, California. These telescopes were chosen because they have both 23 GHz receivers and VLBI capability. Elevation limits of 80° were assumed for all telescopes except those at Bonn and OVRO, for which limits of 78° were used.

The objects set as blind tests are shown in Figs 2a, 3a and 4a. These have been convolved with a two dimensional gaussian beam which has the same FWHM as the central peak of the point source response of the array. The hybrid mapping solutions are shown in Figs 2b, 3b and 4b. In comparing these maps note that the correct solutions represent the maps which would be made with a perfect instrument, that is, with no random or systematic errors, and with complete (u, v) coverage.
Fig. 4 As for Fig. 2, but for Test 3. Contour levels, 5, 15, 25, ... 95% of peak intensity. There are no negative contours ≤ −5%.

The first test is shown in Fig. 2. The conclusions of the mapper, before the solution was revealed to him, were: "The object is a simple double, with no structure outside this double above the 5% level in a field 6 m arc s square. The southern component is slightly brighter than the northern component. The northern component is slightly resolved, with size in the range 0.15–0.3 m arc s, the southern component is barely resolved, or unresolved. The separation of the double is 0.8 ± 0.03 m arc s, in PA $10.5° \pm 1.0°$".

These conclusions are largely correct, the only error being the statement that there is no structure outside the 5% contour of the double. There is a weak component to the north-east, which is in fact reproduced in the hybrid map, but the mapper believed this to be an artefact introduced by the hybrid mapping procedure, that is, he felt that a dynamic range of slightly less than 20 : 1 had been achieved, whereas in fact it is slightly better than this.

The second test is shown in Fig. 3. In this case the conclusions

of the mapper were: "The source consists [...] o bright components (A, B) and two components (C, [...] hich have brightest contours ~5% of the peak of A when c [...] ved with a 0.3 × 0.25 m arc s beam. Component A is unres [...] , although there is some evidence of an intervening compon [...] G) linking it to B. Component G is just picked up at the 5 [...] vel, and is probably real, however, more observations woul [...] needed to confirm this. Component B is unresolved along [...] 122° and resolved along PA 32°. Components C and D are [...] eved to be real. These show up more clearly when convolve [...] ith a larger beam. There is a small possibility that a very we [...] component (H) is real, but this just shows up at the 5% level—more telescopes are needed to give a bigger dynamic range to test this possibility".

In this case the two components about which the mapper expresses doubts (G, H) are not real, and there are two very weak components (E, F) which have been missed altogether. The dynamic range is slightly less than 20.

The final test is shown in Fig. 4. This was a more difficult test than the others because there were no strong features, such as deep minima, in the visibility data, and the area contained within the 5% contour covers a large number of beam areas. This test proved to be too difficult to map with the above six stations, because it is very highly resolved on the long baselines, with only 1/40th of the flux remaining, and as a result the signal-to-noise ratio is very low. The mapper realized that there was very little information on these baselines and attempted to map the object with the five North American stations only. He obtained a fairly good fit to the data in this way, but he concluded that more stations were needed to make a reliable map. A new set of data was produced from seven stations which included the above five North American stations and two additional hypothetical stations at Boulder, Colorado, and Fairbanks, Alaska. The information provided by these seven stations was sufficient to map the object (Fig. 4b). The conclusions of the mapper were:

"The object consists of a bright resolved core about 0.2–0.3 m arc s in size, with extensions to the west in PA 260° ± 1°, 3 m arc s long to the 5% contour, and to the south in PA 170° ± 1°, 3.5 m arc s long to the 5% contour. Both extensions are well resolved perpendicular to their long axes, with half-power widths of ~0.7 m arc s. There are no other components above the 5% contour level".

In each of these blind tests the hybrid map is a good representation of the object, and if these were real objects, most of the interesting astrophysics would be correctly inferred from the hybrid maps. The procedure did not fail in any case, that is, produce a final map with substantial errors.

Conclusion

The blind tests show that it is possible to make maps from completely uncalibrated visibility data in which both the amplitudes and the phases have substantial systematic errors and realistic random noise. A dynamic range of 20 can be obtained using an array of six or seven telescopes.

This procedure should prove invaluable for both VLBI and aperture synthesis mapping at high frequencies, where the effects of the atmosphere on both the phase and the amplitude can be severe. It opens up the wavelength range available for VLBI mapping through 1 cm into the millimetre region, where the most severe problems are atmospheric absorption and telescope pointing. The procedure is not limited to radio frequencies. The only limitation is that fringes of sufficiently high signal-to-noise ratio must be detectable in a time which is short compared with the time for phase and amplitude changes.

Single channel recordings of K⁺ currents in squid axons

Franco Conti

Laboratorio di Cibernetica e Biofisica, CNR I-16032 Camogli, Italy

Erwin Neher

Max-Planck-Institut für biophysikalische Chemie, D-3400 Göttingen, FRG

Ionic currents from individual K⁺ channels in squid axon membrane have been recorded. At hyperpolarizing membrane voltages, unit events occur as widely spaced rectangular pulses with short interruptions. The frequency of occurrence of the units increases strongly when the membrane is depolarized.

ELECTRICAL excitability is conferred on the nerve membrane through the voltage-dependent opening and closing of ion-specific membrane pores or channels[1,2]. Their existence has been established, on the basis of toxin binding[3] and by noise analysis[4–7]. Recently, it has become possible to record electrical signals directly from individual chemically activated channels[8]. These measurements confirmed many of the conclusions drawn from noise analysis and provided a very detailed kinetic

description of channel gating in acetylcholine-activated channels. Here, we report the measurement of discrete contributions to the ionic current in squid axons, displaying the kinetics of opening and closing of single K^+ channels. Some of the known properties of K^+ channels are illustrated on the single channel level, and some more detailed features of the elementary current contribution are indicated.

Experimental arrangement

Short sections (3–4 cm long) of large axons (diameter > 500 μm) were internally perfused with a technique similar to that developed by Tasaki et al.[9] as illustrated in Fig. 1. During preliminary perfusion with a standard K^+-rich solution, the axon was internally treated with pronase (Calbiochem grade B) at a concentration of 1 mg ml^{-1} until the inactivation of voltage-clamp Na^+ currents was reduced to about one-half[10]. This procedure usually took 10–15 min. The internal perfusion was then switched to a low ionic strength medium with the following composition (mEquiv. l^{-1}): 20 Na^+, 1 K^+, 2.15 phosphates, 15.8 F^-, 1 Cl^-, pH 7.8–8. The external medium was also changed to a high K^+ solution with the composition (mM): 460 KCl, 50 $CaCl_2$, 1 Tris-HCl, pH 8. Tetrodotoxin at 3×10^{-7} M was added
Fig. 1 Experimental set-up. *a*, Mechanical arrangement built onto a Perspex block with airgaps (Air), a platinum-coated silver block (Ag) for cooling and electrical grounding, a Ag–AgCl electrode for external voltage recording (VE), perfusion inlet cannula (PI) with a sliding internal electrode assembly (EA), perfusion outlet cannula (PO) and patch pipette (PP). The sliding electrode assembly (EA) consists of a 80-μm platinized wire for internal current injection and a 80-μm o.d. glass capillary with floating Pt wire for internal voltage recording. It is kept inside the PI cannula in the early stage of perfusion. Perfusion is started with the aid of a long outlet cannula (not shown) inserted through PO over the length of the axon until it overlaps with PI. During perfusion, constant hydrostatic pressure is maintained in the axon by maintaining a drop of constant diameter at the outlet through a suction pipette (SP). After longitudinal insertion, the patch pipette (PP) is laterally advanced towards the membrane by means of a motor-driven micromanipulator. The airgaps are 2 mm wide; the immersed part of the axon is ~10 mm long. *b*, Schematic diagram of standard voltage clamp and patch clamp circuit (PCC). The numbers refer to equivalent points in *a*.

to the external medium to suppress Na^+ currents. The chamber and the inflowing external solution were cooled to 5 °C using a Peltier cooler. An L-shaped pipette for patch recording was introduced longitudinally through a specially designed perfusion-outlet cannula (for details see Fig. 1). The patch pipette and the electrical circuit connected to it were similar to those described previously[8] except for the following modifications. The pipette had a 90° bend 100–200 μm from its end and a

prolonged shank ~15 mm long and 100–200 μm in diameter. This required the insertion of a 50-μm floating platinum wire for its whole length, to reduce the internal resistance. The pipette contained low ionic strength internal perfusion medium; its resistance was 50–100 MΩ. The virtual ground circuit and a shield to the pipette holder were driven by the output of the voltage follower to the internal (clamp) potential recording. Thus, the pipette interior followed changes of potential inside the axon. A compensation circuit was included to remove slow drifts in d.c.

The arrangement outlined above was dictated by considerations on the resolution of the measurement. A high driving force for K^+ ions is required in the voltage range of interest, where voltage-dependent gating occurs (−10 to −40 mV); thus, a positive equilibrium potential is indicated. To achieve low background noise, a good seal must be established between pipette and membrane and this rules out any approach from the outside, where the Schwann cell layer obstructs easy access, and suggests the use of low ionic strength internal solutions. In this way, seal resistances as large as 300 MΩ could be obtained.

On the other hand, the arrangement chosen has two serious disadvantages: low ionic strength implies large series resistance in the axon interior, and consequently, a strong spillover from the whole cell clamp arrangement into the patch measurement unless the internal voltage recording electrode is carefully positioned very close to the patch. Longitudinal insertion of the patch electrode brings with it a large stray capacitance between pipette interior and the axon, which increases the background noise at higher frequencies. Therefore, recordings are probably not meaningful above 500 Hz bandwidth and responses to jumps in membrane voltage are contaminated by large and long-lasting artefacts.

Effects of varying membrane potential

In the conditions chosen, reversal potentials for K^+ currents were between +70 and +100 mV as estimated from potential measurements after removal of K^+ inactivation. For a macroscopic characterization, the axon was normally kept at its steady-state resting potential, which ranged between +50 and +70 mV. It was intermittently clamped for short periods (≈1 s) to −50 mV, to which depolarizing steps of 30–120 mV amplitude were added. K^+ inward currents developed during the pulses and were followed by large, long-lasting inward tail currents on return to −50 mV. In Fig. 2c, the amplitudes of the macroscopically measured tails are plotted against the membrane voltage during the preceding pulse. This yields, basically, the steady-state activation curve of the K^+ system. The curve is shifted along the voltage axis, as compared with the standard Hodgkin–Huxley axon[1]. This shift is probably the effect of the low internal ionic strength (in analogy to ref. 11).

On the patch records, dramatic changes can be observed when the membrane voltage is shifted across the range of channel activation. Starting from a very strongly depolarizing voltage, that is, one close to the K^+ equilibrium potential, small, slow fluctuations are observed. They increase in size as the membrane voltage is slowly made more negative (Fig. 2a, traces at +34, +17 and −8 mV). However, within a narrow voltage range, fluctuations decrease very rapidly (Fig. 2a, traces at −19 mV and below). They appear as discrete waveforms at voltages lower than −10 mV, and become progressively more rare as membrane voltage is further lowered. We interpret these discrete, one-sided (inwardly directed) fluctuations as contributions from individual K^+ channels, which cannot be seen easily at more depolarizing voltages because there are many channels on the patch which are open simultaneously. Their openings and closings overlap to give large fluctuations. However, at hyperpolarizing voltages most channels are closed. The rare event of channel opening can be observed above a quiet background.

Figure 2b shows the variance, σ^2, of traces, like those in Fig. 2a plotted against voltage V, together with the expectation of a very simple model: given that there are N active, independently
Fig. 2 *a*, Recordings of patch current at different membrane potentials (as indicated in mV). Temperature, 5.5 °C, pipette resistance before approaching the membrane, 100 MΩ, after approach, 280 MΩ. *b*, Variance of segments like those in *a* (bandwidth, 250 Hz) plotted against membrane potential. Membrane voltage was changed in irregular steps several times across the whole voltage range in both directions. Different symbols refer to different sweeps. *c*, Tail currents at −50 mV holding potential as a function of membrane potential during the preceding test pulse, which was 30 ms in duration. A small correction was applied to the three lowermost points to account for incomplete settling of the current response during the test pulses. The curve in *c* was drawn by eye through the experimental points and was used to represent $P(V)$ for the calculation of variance (equation (1)) in *b*. Only one free parameter could be adjusted to fit the data in *b*, which was the product $N\gamma^2$ of equation (1). It was given a value of 2×10^{-21}. This, together with $\gamma = 17$ pS (see below), yields an N of 7. Thus, there were about seven active channels under the pipette.
Fig. 3 Several traces of patch recordings at higher time resolution. *a* was taken at −25 mV membrane potential, *b* at −35 mV. The elementary events seem to be bursts of closely spaced pulses. Histograms of open times and closed times of this and nine similar records (a total of 270 bursts) were calculated. The open times were distributed approximately exponentially with a mean open time of 6.1 ms. The closed times had a bimodal distribution: short intervals corresponding to interruptions within a burst were superimposed on an approximately exponential distribution of long intervals corresponding to intervals between bursts. The two classes of intervals could be well separated. There were, on average, 0.65 short intervals per long interval. However, the mean duration of the short intervals was close to the time resolution limit of the measurement. Therefore, a great number of short intervals had probably been missed in the analysis. Their number was estimated by extrapolation of the closed time histogram, assuming that the short intervals are distributed exponentially. This gave a corrected number of 1.8 interruptions per burst. For consistency, this correction necessitated a further correction regarding the mean open time of the short pulses, because a given burst was then assumed to be divided into more pulses. The corrected value for the mean open time was 3.5 ms.

operating channels, each with a probability $P(V)$ of being in its open state with conductance γ, the variance of the current record should be

$$\sigma^2 = \sigma_b^2 + N(1 - P(V))P(V)\gamma^2(V - V_K)^2 \qquad (1)$$

where V_K is the K^+-equilibrium potential, and σ_b^2 the background noise in the absence of any channel openings. The solid line in Fig. 2b is calculated according to equation (1) with $P(V)$ derived from Fig. 2c (see Fig. 2 legend) assuming V_K to be $+90$ mV and σ_b to be constant. Various factors can make the prediction of equation (1) inaccurate: (1) σ_b is probably not a constant; (2) the macroscopic activation curve was obtained in conditions of roughly constant K^+ inactivation[12], whereas changes in K^+ inactivation, although expected to be small in the voltage range covered, may have occurred during the long-lasting polarizations of Fig. 2a; (3) a constant value of γ is not appropriate for characterizing the current–voltage relationship of K^+ channels for strongly asymmetric transmembrane ionic concentrations such as those used in the present study. The fit of the data of Fig. 2b with the solid line is therefore as good as it can be and is evidence that the fluctuations of Fig. 2a are indeed derived from the random open–close transitions of K^+ channels.

Properties of single channel fluctuations

Regarding the shape of the elementary event, one can see waveforms resembling square pulses at hyperpolarizing voltages (see, for instance, Fig. 2a, lowermost trace). Their mean amplitude is approximately 1.6 pA (range 1.4–2.0 pA). At closer inspection, however, the majority of the waveforms show short interruptions and appear as bursts of short pulses. Examples are seen in Fig. 2a (trace at -25 mV), and, at better resolution, in Fig. 3. Statistical analysis of time intervals in the records[13], correcting for limited time resolution (see Fig. 3 legend), shows that there are on average 2.8 short pulses per burst, each with a mean open time of about 3.5 ms. The mean duration of the interruptions is 1.3 ms. Thus, a burst lasts, on average, 12 ms. These numbers are obtained from pooled data at membrane potentials between -20 and -35 mV. In this range, elementary events are rare enough to be well separated in time. The probability of any channel being in the open state is >0.03 (see Fig. 2c). The frequency of appearance of bursts increases strongly with voltage. The other parameters given above, however, do not change significantly in the narrow voltage range studied. At more strongly depolarizing potentials, whenever elementary events overlap, it is virtually impossible to reach any conclusion about the waveform, due to the flickering nature of the elementary event and limited resolution.

The records shown above come from one of the patches with the highest activity that we have encountered. Generally, the degree of activity varied widely, even on patches (≈ 1 μm diameter) which were immediately adjacent. A good fraction of patches did not, indeed, show any activity at all. This inhomogeneity enabled us also occasionally to observe discrete fluctuations at more strongly depolarized potentials. However, these were chance observations and were not further analysed.

Analysis of results

The examples given clearly show that it is possible to resolve single channel currents of the squid axon K^+ system, although, compared with other single channel measurements, such as

endplate channels, it is much harder to obtain adequate resolution due to: (1) difficulty in obtaining good contact between the glass pipette and the inner membrane surface, (2) high current density in squid axon membrane and numerous associated artefacts, and (3) uniform activation of channels over both the seal and patch area, producing excess background noise and non-uniformity in single channel amplitude.

Unit current values were as large as 2 pA at about -25 mV. Thus, assuming ohmic behaviour and a reversal potential of $+90$ mV, a single channel conductance of 17.5 pS is obtained. This value cannot be considered adequate to describe K^+ channel conductances in normal physiological solutions because our measurements were done in very unphysiological and asymmetric ionic conditions. Assuming that the IV characteristic of open channels obeys the constant field equation, one can calculate from the current value above a single channel K^+ permeability of $p = 2.85 \times 10^{-14}$ cm^3 s^{-1}. With this value, the chord conductance at -50 mV, which is expected to describe physiological conditions, is 9–11 pS, assuming p_{Na}/p_K values of 0.01 or 0.05, respectively[14], and an intracellular K^+ concentration of 400 mM (ref. 15). This is very close to that obtained from noise analysis[4].

The mean channel open time (burst duration) of 12 ms seems rather long. However, it has also been observed in macroscopic measurements that K^+ tail currents are prolonged in conditions of high extracellular K^+ (ref. 16). For instance, at -50 mV, we observed exponentially decaying tail currents with $\tau = 8$ ms after depolarizing pulses. Thus, the duration of the elementary events is in the time range expected from macroscopic currents.

The short interruptions within a burst are indicative of some closed channel state which is in relatively fast equilibrium with the open state. For a tentative interpretation, a sequential reaction scheme is assumed:

$$\cdots \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} C_2 \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} C_1 \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} O \qquad (2)$$
where C_2 and possible other states to its left are closed states, C_1 is a temporarily or transiently closed state, and O is the open state. Bursts of activity are predicted if k_2 is much smaller than all the other rates. These, then, can be calculated easily from our data. The mean number, n, of interruptions within a burst is k_1/k_{-2} (ref. 17) and the mean time of the short interruptions within a burst is $1/(k_{-2} + k_1)$, which is the mean lifetime of state C_1 (refs 13, 17). With the numbers given above, we obtain $k_{-2} = 274$ s^{-1}, $k_1 = 493$ s^{-1} and $k_{-1} = 285$ s^{-1}. The Hodgkin–Huxley model for the K^+ currents can be considered a special case of a sequential model[18] like scheme (2). As such, it predicts a grouped appearance of pulses. However, quantitatively, the predictions are very different from what is observed. For instance, the mean number, $\bar{n}$, of interruptions within a group would be $\bar{n} = k_1/k_{-2} = \alpha_n/3\beta_n = n_\infty/3(1 - n_\infty)$, where α_n, β_n and n_∞ are the Hodgkin–Huxley variables. For $n_\infty \leq 0.03^4 \approx 0.4$, this is smaller than 0.25. The number measured, in contrast, is 1.8. Thus, a Hodgkin–Huxley type mechanism cannot be invoked to explain the single channel measurements.

Model for antenatal diagnosis of β-thalassaemia and other monogenic disorders by molecular analysis of linked DNA polymorphisms

P. F. R. Little*, G. Annison, S. Darling & R. Williamson

Departments of Paediatrics and Obstetrics, University College Hospital Medical School, London WC1, UK

Polymorphisms of DNA restriction sites within the human fetal globin genes have been used to identify chromosomes that carry β-thalassaemia genes in individuals heterozygous for this disease. This has allowed an antenatal diagnosis for β-thalassaemia to be carried out by observation of the pattern of the inherited polymorphism of a linked DNA sequence not involved in the genetic pathogenesis of the disease. In the populations we have investigated there is no constant pattern of polymorphism that segregates with the β-thalassaemia gene. The use of linked polymorphisms should, therefore, be applicable to antenatal diagnosis both of β-thalassaemia and of any other single-gene defect for which there is a DNA probe specific for a sequence linked to the affected locus.

GENETICALLY determined human diseases are becoming increasingly important in modern medical practice. The incidence of monogenic disorders is geographically variable, but in Europe approximately 1 in 100 of the newborn population is affected[1]. There are now two clinical approaches to such disorders: treatment of symptoms of the disease or prevention of the disease by antenatal diagnosis and therapeutic abortion.

Antenatal diagnosis of a monogenic disorder is generally attempted by obtaining fetal cells which express the protein abnormality. For many enzyme defects, antenatal diagnosis is by analysis of enzyme activity in fetal fibroblasts. These may be isolated from the amniotic fluid by the relatively simple procedure of amniocentesis. This strategy is possible for about 60 of more than 1,000 known single-gene disorders[2,3]. However, it is not possible for β-thalassaemia as fibroblasts do not synthesize haemoglobin. For the haemoglobinopathies it is necessary to obtain fetal red blood cells, a technically difficult procedure which carries a 7% risk of abortion[4]. A sample of fetal blood is obtained from a placental vessel and its ability to synthesize β-globin estimated *in vitro*[5]. The β-thalassaemias are characterized by low or absent synthesis of β-globin chains.

The thalassaemias also provide an example of an alternative approach to antenatal diagnosis—the direct analysis of genes in DNA isolated from fetal fibroblasts obtained by amniocentesis. This analysis is most straightforward when the disease is caused by a gene deletion, as for α-thalassaemia[6-11] or δβ°-thalassaemia[12], but such an approach is not possible for the common forms of β-thalassaemia, as the β-globin gene is present[13,14].

Kan and Dozy used a different approach for the antenatal diagnosis of sickle-cell disease[15,16]. They demonstrated linkage between the sickle-cell globin mutation in the β-globin gene and a restriction site polymorphism approximately 5 kilobases to the 3' side of the gene, using a plasmid containing the β-globin gene sequence as a probe.

We show here that it is possible to perform an antenatal diagnosis for β-thalassaemia by detecting restriction enzyme site polymorphisms that are shown to be segregating within the family at risk. The polymorphism is detected as variation in the band pattern obtained in a Southern blot after digestion with the

appropriate restriction enzyme[17-19]. We have used a probe, not for the affected gene (β-globin) but for a neighbouring gene, γ-globin. In principle this could allow the antenatal diagnosis of any disease caused by a single-gene defect for which there exists a DNA probe specific for the affected locus, or for a locus close enough to be linked genetically.

Results

Jeffrys[20] and Tuan *et al.*[21] have used Southern blot hybridization to show that the two human fetal globin genes are polymorphic for a restriction site for the enzyme HindIII (and thus HsuI, which recognizes the same AAGCTT sites)[22]. Either the ^{G}γ- or ^{A}γ-globin gene, or both, may contain a cleavage site, at the same position within the large intron (Fig. 1)[23].

We have studied families and individuals from Cypriot, Italian and Indian thalassaemic populations. γ-Gene polymorphisms were identified on the chromosomes carrying the thalassaemia genes in a given family, and antenatal diagnosis was then performed by detecting the pattern of chromosome-specific polymorphism inherited by the fetus. Diagnosis of thalassaemics was by familial
Fig. 1 *a*, The structure of the human ^{G}γ-^{A}γ-δ-β-globin gene loci[26-30]. The positions of polymorphic restriction sites marked are taken from refs 20, 21 and 29 for *Pst*I and *Hsu*I (*Hin*dIII), from ref. 16 for *Hpa*I, from ref. 31 and R. A. Flavell (unpublished data) for *Kpn*I and from Y. W. Kan (unpublished data) for *Bam*HI. Only a single intron is shown within each structural gene; the position of the smaller intron is now shown. Sizes are in kilobase pairs. *b*, Sizes of fragments generated by *Hsu*I and *Bgl*II sites around and within the ^{G}γ- and ^{A}γ-globin genes. Hs, *Hsu*I (*Hin*dIII); Bg, *Bgl*II.

* Present address: Division of Biology, California Institute of Technology, Pasadena, California 91125.
Fig. 2 Autoradiographs of Southern blots demonstrating polymorphism of *Hsu*I sites associated with the $^G\gamma$- and $^A\gamma$-globin genes. *Hsu*I digests of DNA from people with restriction patterns G−−/A−−, G+−/A−−, G++/A++, G+−/A+− and G++/A+− (where G+− indicates that one $^G\gamma$-globin gene has the *Hsu*I site and one does not, and so on) are shown (*a*) as well as *Hsu*I/*Bgl*II double digests of the G++/A++ and G+−/A+− persons (*b*). 10 μg of each human DNA was digested to completion and run on a 1% agarose gel. Slot dimensions were 0.75×0.2 cm, voltage gradient was 2 V cm^{-1}, run time was 17 h and the running buffer was 10 mM Tris, 0.25 M NaAc, 1 mM EDTA, pH 7.7 supplemented with 0.5 μg ml^{-1} ethidium bromide. After running gels were denatured, neutralized, transferred and filters hybridized to radioactive *p*H γGl, a pCRI recombinant plasmid containing 500 base pairs of DNA was made on a template of mRNAγ (ref. 32). All methods are as described in refs 17, 26, 27. Growth and preparation of the plasmid was at Category I* as recommended by the UK Genetic Manipulation Advisory Group.

history, in particular the existence of a homozygous thalassaemic child, and also by red cell indices and HbA₂ levels. No attempt was made to classify the β-thalassaemia further.

The fragment patterns generated by the presence or absence of particular *Hsu*I sites associated with the γ-globin genes are shown in Fig. 2. To confirm that the pattern of $^G\gamma$-fragments has been correctly interpreted, we have also analysed double digests with *Hsu*I plus *Bg*/II. Figure 1*b* shows the location of the *Bg*/II site within the larger ($^G\gamma$)*Hsu*I fragment. The double digest fragment pattern for persons identified by *Hsu*I digest as having restriction sites G+− and G++ is precisely as predicted (Fig. 2).

We have examined individual families with thalassaemia to determine the familial pattern of *Hsu*I polymorphisms linked to the β-thalassaemia genes. Restriction sites of two families are illustrated in Fig. 3. Family A, of Cypriot origin, consists of a β-thalassaemia carrier mother (pattern G+−/A−−), a carrier father (G+−/A+−), a carrier daughter (G+−/A+−) and a homozygote β-thalassaemic son (G−−/A−−). Genotypes may be assigned as follows: the son can only be $\dfrac{-\,-}{-\,-}$, which indicates both parents must contain a haplotype $-\,-$. Hence the mother can only be $\dfrac{+\,-}{-\,-}$, the father $\dfrac{+\,+}{-\,-}$ and the daughter $\dfrac{+\,+}{-\,-}$. As the son is a homozygous β-thalassaemic his genotype can only be $\dfrac{-\,-\ thal}{-\,-\ thal}$ and the mother $\dfrac{+\,-}{-\,-\ thal}$, the father $\dfrac{+\,+}{-\,-\ thal}$ and the daughter $\dfrac{+\,+}{-\,-\ thal}$.

Family B consists of a β-thalassaemia carrier mother (G+−−/A−−−) of Italian origin, a carrier father (G+−−/A+−−), a homozygous β-thalassaemic daughter (G++/A+−) and a carrier son (G+−

/A−−). The daughter can only have a genotype $\dfrac{+\,-}{+\,+}$, the son $\dfrac{+\,-}{-\,-}$ and the mother $\dfrac{+\,-}{-\,-}$. The father could be either $\dfrac{+\,+}{-\,-}$ or $\dfrac{+\,-}{-\,+}$. The former genotype must be correct as this is the only genotype that contains the haplotype $+\,+$ that is inherited by the daughter. Thalassaemia genes are assigned as follows. The daughter can only be $\dfrac{+\,-\ thal}{+\,+\ thal}$. Thus the father must be $\dfrac{-\,-}{+\,+\ thal}$. The mother must have donated the $+\,-$ chromosome and therefore must be $\dfrac{-\,-}{+\,-\ thal}$. The son has therefore inherited $\dfrac{-\,-}{+\,-\ thal}$.

From these data it is clear that it is possible to follow a β-thalassaemia gene through some families by identifying the *Hsu*I γ-globin gene polymorphisms.

We studied an Asian Indian family requesting antenatal diagnosis. The family comprised the mother and father, both of whom are β-thalassaemia carriers with restriction patterns G+−/A−−, and a homozygous β-thalassaemic child who is also G+−/A−− (Fig. 4). Amniocentesis and fetal blood sampling were carried out on the mother. DNA from 20 ml of amniotic fluid was analysed and found to be G−−/A−−. As we know that the homozygous thalassaemic child has a restriction pattern G+−/A−−, and therefore a genotype $\dfrac{+\,-\ thal}{-\,-\ thal}$, we can conclude that the fetus must be β-thalassaemic carrier, genotype $\dfrac{-\,-\ thal}{-\,-}$. It is not possible to determine the thalassaemic genotypes of the parents: the son has the genotype $\dfrac{+\,-\ thal}{-\,-\ thal}$, but as both parents have the same genotype, $\dfrac{+\,-}{-\,-}$, it is impossible to determine the parental origin of the β-thalassaemia chromosomes. One parent must be $\dfrac{+\,-\ thal}{-\,-}$, the other $\dfrac{+\,-}{-\,-\ thal}$.
Fig. 3 Inheritance of *Hsu*I polymorphisms. DNA samples from families A and B respectively were analysed for intragenic *Hsu*I sites as described in Fig. 2 legend. Restriction patterns observed are detailed. Sizes are in kilobase pairs.

Analysis of the fetal blood sample carried out in parallel showed that the diagnosis obtained using direct gene linkage analysis is correct (Fig. 5). The fetus was synthesizing β-globin at a level appropriate to a β-thalassaemia carrier, with a β/γ synthetic ratio of 0.039. In our laboratory the β/γ ratio for homozygous β-thalassaemia is generally not greater than 0.017, the β-thalassaemia carrier β/γ ratio is in the range 0.022–0.05 and the normal range is between 0.045 and 0.10 (unpublished data). The fetus has not yet come to term.
Fig. 4 Antenatal diagnosis of a case of β-thalassaemia. DNA from an Indian family and their unborn child was analysed for γ-globin intragenic *Hsu*I sites. DNA from fetal cells was obtained as follows. Amniotic fluid (20 ml) was centrifuged at 10,000*g* for 10 min. The pellet of cells was taken up in 200 μl 0.15M NaCl, 0.1M EDTA, *p*H 10.5. The cells were lysed by adding SDS to 0.1% (w/v). Proteinase K was added to 10 μg ml⁻¹ and the suspension incubated at 37 °C for 4 h. The DNA was extracted with an equal volume of phenol (redistilled under N₂ gas and equilibrated with 0.15M NaCl, 0.1M EDTA *p*H 10.5), and then with an equal volume of chloroform/octan-2-ol (24 : 1 v/v). DNA was precipitated with two volumes of ethanol. The whole of the DNA sample (estimated at between 2–5 μg) was digested with *Hsu*I and run on the transfer gel and analysed as described in Fig. 2 legend.

Population considerations

Human populations differ in frequencies of polymorphic sites[24]. Should this be the case for the *Hsu*I polymorphisms studied here, and if populations exist that have low frequencies of these polymorphisms, then this would limit their general usefulness for diagnosis.

We have analysed the *Hsu*I restriction sites of 21 Cypriots, 31 Italians and 14 Indians (Table 1). All are thalassaemia carriers. It is not possible to assign genotypes to all restriction patterns, nor is it possible in every case to identify the chromosomes carrying the thalassaemic gene. Therefore, we cannot draw conclusions about the frequency of polymorphisms on the normal compared to the thalassaemic chromosomes. The data are too sparse for more general conclusions to be made regarding the frequency of the various genotypes, and whether linkage disequilibria exist. However, it is likely that the greater degree of heterogeneity of the Italian thalassaemic population would make the diagnostic approach we have used more commonly applicable than with the Indian or Cypriot populations.

Conclusions

We have shown that it is possible to use two specific linked polymorphisms that are present in a particular family to perform an antenatal diagnosis by DNA restriction fragment analysis. The method described here may be applied to any defective gene for which a probe exists, or where a probe for an adjacent gene exists, as in this case. The only condition must be that either a homozygote or a normal child must have been born to the family at risk, or that the disease be diagnosable in a heterozygous state to allow identification of the affected chromosome by family analysis. There are certain couples without appropriate restriction sites, for whom chromosomal assignments are not possible.

Most genetic diseases do not have a high incidence, and it will be difficult to establish the existence of the linkage disequilibria seen for thalassaemia and sickle cell anaemia. Therefore, it seems likely that antenatal diagnosis of most gene defects will not be possible using a single linked polymorphism. The estimate of Jeffrys[21] that 1 base in 100 is different between any two

Table 1 Frequency of occurrence of *Hsu*I polymorphisms in the γ-globin genes in various thalassaemia carrier populations

Restriction pattern	Cypriot	Italian	Indian
G++/A++	—	4	—
G++/A+−	—	2	1
G++/A−−	—	1	—
G−−/A−−	13	6	2
G+−/A−−	7	6	7
G+−/A+−	1	12	4
Frequency A+	0.023	0.35	0.18
G+	0.19	0.52	0.46
Total (individuals)	21	31	14

Frequency of occurrence of the *Hsu*I site in the ᴬγ- and ᴳγ-globin genes were calculated from restriction digest patterns shown in Fig. 2.

healthy humans who are not related suggests that any coding gene, defective or normal, will be surrounded by a unique set of DNA polymorphisms. The technique we have described here should be generally applicable for monogenic human genetic diseases.

Two questions remain. First, how closely linked do polymorphisms have to be to reduce the risk of misdiagnosis due to meiotic recombination? There is no specific information on the rate of crossing over that would be expected over the 20-kilobase section spanning the ᴬγ- to β-globin gene distance. It has been estimated that meiotic recombination occurs with a frequency of 1 per 10⁸ base pairs per generation[25]. From this it is clear that the chance of misdiagnosis due to crossing over in a single generation is extremely small. It is not yet possible to estimate the effect of mitotic recombination.

Second, how common are DNA polymorphisms in the human genome? The positions of eight polymorphisms which have been detected using DNA probes specific for the γ- or β-, δ-globin genes are shown in Fig. 1. The low frequency of recombination should allow large pieces of DNA to be scanned for useful polymorphisms. The human β-like globin locus is about 50 kilobases long. Distances greater than 1,000 kilobases could in principle be scanned for linked polymorphisms using cloned genomic DNAs or cDNAs as probes.
Fig. 5 CM-Cellulose elution pattern of globin proteins from fetus diagnosed in Fig. 4. Red cells obtained by fetoscopic fetal blood sampling were labelled with ³H-leucine, lysed, globin prepared and co-chromatographed with cold cord blood carrier globin on CM32 columns in 8M urea and a phosphate gradient according to ref. 33. The γ-, β- and α-globin peaks were located by optical density (not shown) and by their radioactivity. Ratios were determined as described elsewhere. (Ref. 5 and Matsakis *et al.* in preparation.)

Note added in proof: Kan et al. have recently shown[36] that β^0—thalassaemia in Sardinia may be diagnosed by the presence of BamHI site 9.3 kilobases to the 3' side of the β-globin gene. Unaffected Sardinians normally have a BamHI site at 22 kilobases from the β-globin gene.

Sea urchin histone mRNA termini are located in gene regions downstream from putative regulatory sequences

Christopher Hentschel, Jean-Claude Irminger, Philipp Bucher & Max L. Birnstiel

Institut fur Molekularbiologie II der Universität Zürich, Hönggerberg, 8093 Zürich, Switzerland

S_1 *nuclease mapping of the Psammechinus miliaris embryonic histone mRNAs locates the 5' termini in or adjacent to a short sequence homology (5'pyCATTCpu3') downstream from the putative RNA polymerase II regulatory sequence (5'TATAAATA3') or related sequences. The 3' termini map just after a sequence containing GC-rich hyphenated dyad symmetry, a feature of most known terminator sequences.*

THE rapid growth in recombinant DNA technology has led to the isolation of an increasing number of cloned eukaryotic genes, and in many cases the DNA sequences of substantial areas of the genes have been determined. The mode of action of functional elements of the sequence remains unclear. Analogy with prokaryotic systems, however, leads us to expect that several non-coding regulatory sequences are involved in such functions as transcription, RNA maturation, translation and DNA replication. In eukaryotes, one might also expect to find a set of more complex regulatory sequences involved in nucleo-cytoplasmic transport, topological segregation of RNA species in the cell, and even in the ontogenic regulation of genes in specific cells of the fertilized egg.

We have described several available approaches towards the identification of putative regulatory sequences using the sea urchin histone gene clusters. Because they are repeated and hence probably comprise a complete functional unit, these provide a particularly opportune starting material[1,2]. Two prerequisite sequential analytical steps are envisaged: (1) RNA mapping coupled with comparative sequence analysis to help identify sequence elements which are conserved in equivalent topological locations of the genes, and hence are presumably important in some way to their expression, and (2) functional testing of the proposed regulatory sequence and their mutant counterparts in a surrogate genetic system which operationally recognizes the sequence[3,4].

We describe here results relating to the first of these prerequisites for the cloned and almost fully sequenced 6-kilobase histone repeat from *Psammechinus miliaris* (h22)[5,6]. The h22 repeat was previously predicted as being part of an embryonic programme due to both its high reiteration frequency and the homology of its deduced histone products with genuine embryonic-type histones from other sea urchins[6]. This view has been confirmed at the RNA level by the finding that h22 hybridizable RNA derived from early embryonic stages produces hybrids completely resistant to excess S_1 nuclease activity (see below). We were therefore prompted to determine where these mRNAs mapped on the h22 sequences relative to several conserved sequence elements flanking the histone-coding regions of the genes[7–9]. The most ubiquitous of these, the 'Hogness box' (ref. 10), is found upstream from several histone- and other polymerase II-transcribed genes and comprises a sequence related to the consensus form 5'TATAAATA3'. About 20 nucleotides downstream from this sequence, there is a sequence related to 5'pyCATTCpu3' (ref. 8). A second pair of homology blocks is found downstream from sea urchin histone gene-coding sequences, including the five h22 genes (see below); they comprise a large block closer to the protein termination codon, and are characterized by a 16-nucleotide GC-rich hyphenated dyad symmetry element separated by a short, relatively AT-rich stretch from a smaller homology with a consensus sequence 5'CAAGAAAAGAA3' (ref. 9).
Fig. 1 Autoradiogram of S_1 mapping of the H2B (*a*) H2A (*b*). H3 (*c*) and H1 (*d*) mRNA 5′ termini. Mapping was essentially as described by Berk and Sharp[11] with the following modifications[13]. Approximately 1.5 pmol of, respectively, *Hinf*/*Hpa*II, *Hae*II/*Xho*I, *Hae*III/*Hpa*II and *Hinf*/*Hpa*II restriction fragments of h22 insert DNA[6], which span the mRNA 5′ termini from within the coding sequence and 5′ ^{32}P-labelled at the internal sites were used. These were hybridized for 3 h at 48 °C and 250 μg of RNA obtained by phenol/chloroform extraction of *P. miliaris* embryos at the 128-cell stage of development in 50 μl of formamide 80%, 0.4M NaCl, 40 mM MOPS, *p*H 6.7, and 1 mM EDTA. After dilution with 9 volS_1 nuclease buffer (0.25 M NaCl, 0.03 M sodium acetate, *p*H 4.6, 1 mM ZnSO$_4$), hybrids were digested with 10 units of S_1 nuclease purified as described by Vogt[33] at either 37 °C for 1 h (*a*,*b*,*d*) or 45 °C for 2 h (*c*). Protected DNA was precipitated with 2 vol ethanol, washed with 70% ethanol, vacuum dried and dissolved in formamide 80% (v/v), 0.05% bromphenol blue/ xylene cyanol and 1 mM EDTA. Samples were electrophoresed at 30 V cm^{-1} on 8% acrylamide, 8 M urea, thin sequencing gels[16], in parallel with G cleavage fragments [15], of the end-labelled restriction fragment and *Hpa*II-cut 5′ end-labelled pBR322 (ref. 29) for size orientation (not shown). Autoradiography of the gel was with prefogged Kodak XR-5 film and intensifying screen at — 70 °C (ref. 34). The region of the autogradiogram shown has been aligned in part with the sequence of the protected coding strand. Note that the G cleavage fragments represent a set of fragments shorter by one nucleotide than a G in the sequence. Indicated sequence positions are from the initiator codon with conserved sequences boxed (see text). Nucleotides corresponding to the 3′ termini of protected DNA are indicated with triangles. In the case of the H3 mapping experiment (*c*), the effect of the more stringent S_1 digestion is illustrated in the overexposed tract.

A knowledge of the location of the histone mRNA termini to these homology blocks is required before we can evaluate their significance in the processes involved in mRNA production.

Mapping of mRNA 5′ termini

Several methods for mapping RNA onto DNA sequences have recently become available. We have studied variants of the Berk/Sharp S_1 nuclease protection methodology[11-14]. The advantages of this technique are due not only to its sensitivity and specificity but also to the fact that both 5′ and 3′ termini can be mapped in heterogeneous RNA preparations. Additionally, we already had good reason to believe that at least in the case of the H4, H2B, H3 and H2A genes no introns existed which might complicate the analysis[6]. In preliminary experiments, the ability of the mRNAs to form completely uninterrupted S_1-resistant hybrids with H22 sequences was tested. These results, and those described below, confirmed this view for all the genes, including the H1.

The H2B and H2A genes were initially selected for mapping experiments. In each case, uniquely 5′-end-labelled restriction fragments were prepared that overlapped the 5′-mRNA termini from the labelled ends which lay within the protein coding region. Hybrids formed between the labelled coding DNA and the homologous mRNAs present in RNA preparations derived

from *Psammechinus* embryos at the 128-cell stage of development were trimmed using S_1. The protected DNA was then analysed on thin sequencing gels using as size markers the respective G cleavage fragments of the unhybridized DNAs[15,16]. Autoradiograms of these gels are shown in Fig. 1(*a*, *b*). As the DNA sequences are known (ref. 8 and unpublished results), the G cleavage fragments provide sufficient information for alignment of the S_1-resistant DNA with the corresponding sequence. Note that only a selected subset of the G cleavage markers are actually aligned in Fig. 1 and that each one comprises a 5′-end labelled fragment up to but not including the G in the sequence, as this is eliminated by the cleavage reaction[15]. The mobility of the 3′-OH-terminated S_1 fragments is very slightly slower than that of their 3′-P-terminated counterparts produced by chemical cleavage. This usually has little effect on alignment as it results in a difference of less than one-half nucleotide spacing[17,18] and would therefore produce a small error compared with the indeterminacy of the ragged 3′ ends of the S_1-resistant DNA [13]. S_1-resistant DNA which had lost even a single 5′ nucleotide would, of course, not be displayed.

Interpretation of the results shown in Fig. 1 requires a knowledge of the exact behaviour of S_1 nuclease at the junction between single strand and hybrid DNA. From preliminary trials, we concluded that the degree of S_1 trimming could vary over a

few nucleotides depending on the severity of the S_1 digestion conditions used, and similar results have been reported by others[14,18]. The variability usually results from a 3'-ragged DNA overhang of one to five nucleotides[12,14,18], and digestion into the hybrid can only be detected in high yield in circumstances which allow selective 'breathing' of the 3' DNA end of the hybrid. In addition to this inherent heterogeneity of the S_1-resistant DNA, it has recently become clear that mRNA 5' termini can, at least in some cases, themselves exhibit microheterogeneity (see, for example, ref. 19) which, if present, would also cause further heterogeneity in the S_1-resistant DNA. The detection of heterogeneous mRNA termini by the S_1 technique is clearly only possible if abundant species are further apart than the spread of the DNA ragged ends, and would need to be confirmed by direct analysis of the capped sequences. The results of the H2A and H2B mapping (Fig. 1 *a, b*) can therefore only locate the region of the mRNA 5' termini to within two or three nucleotides. Even with this limitation, however, it is clear that the 5' ends of these RNAs are adjacent to or within a heptameric region of the high sequence homology found in front of sea urchin histone genes[8], with a consensus sequence 5'pyCATTCPu3'. In the case of the core histones (H4, H2B, H3, H2A) of the variant gene repeats, h19 and h22 of *Psammechinus*, only three mismatches are found to this sequence, two of which occur in the H2B gene of h22 (Fig. 1*a*). Although the exact location of the 5' termini of the H2A and H2B genes cannot be determined from these results, the fact that histone mRNA cap structures are predominantly of the form $7mGpppA^m$ (refs 20, 21) suggests that the most abundant termini will end in an A. In the case of the H2B this constraint suggests that the A of the homology box (at −75) is the pre-dominant terminus. In addition, this location is 23 nucleotides downstream from a Hogness box and it has been suggested that this is, to within a nucleotide, a rule for mRNA 5' termini[10]. In the case of the H2A mRNA (Fig. 2*b*), there are three As (−70, −73, −74) which could fall within the resolution of the S_1 mapping, one of which is (as for the H2B) the highly conserved A of the homology box at −70. However, only the A at −74 fits with the 23 ± 1 rule relative to its Hogness box, so that either the rule is too stringent or the homology box does not define the exact 5' nucleotide.

No evidence for abundant 5'-RNA microheterogeneous species can be discerned from these mapping results for the H2A and H2B mRNAs; at least, not with a range greater than two or three nucleotides, as the protected DNA bands are about this wide. No significant decrease in the size of the main protected bands is obtained by increasing the amount of S_1 nuclease used in the digestion beyond that used for the results in Fig. 1 (*a, b*), suggesting that these are essentially limit digests. Heavy exposure of these highly digested samples, however, revealed that low levels of digestion within the hybrids occurred in these samples at non-random sites, possibly due to breathing of the hybrids and 'nibbling in' at the termini. Such nibbling was clearly observed in a previous study, when very large amounts of S_1 were used[18], and we have observed similar effects when more stringent S_1 digestion conditions were used, particularly at higher digestion temperatures. An example is shown in the overexposed tract in Fig. 1*c*, which maps the H3 5' terminus. In this case, the principal protected DNA bands were a few nucleotides shorter relative to the homology box than in the H2A and H2B mapping experiments. We cautiously interpret this result as being consistent with the A at −56 being the most abundant 5'-coded nucleotide of the H3 mRNA. This location also lies appropriately downstream from a Hogness box.

Although the exact locations of the 5' termini of the H2A, H2B and H3 mRNAs are not defined by these S_1 mapping results, it seems clear that the termini are topologically related to conserved sequence boxes in front of the genes, suggesting that these sequences are in some way related to the generation of the termini. In the case of the remaining two genes of the h22 repeat (H1 and H4), the degree of homology to the 'consensus' form of the homology boxes is poorer than for the H2A, H2B and H3

genes. Nevertheless, the same general location is observed for the 5' termini of these mRNAs relative to their somewhat deformed homology boxes. Figure 1*d* shows the S_1 mapping of the H1 5' terminus. The cap box in the case of this gene (5'pyCACTTpu3') shows a five out of seven fit to the consensus 5'pyCATTCpu3' sequence, whereas the region considered to be the Hogness box for this gene fits in five out of eight positions. In the case of the H4 mRNA, the region of 5' terminus had already been tentatively located by comparison with its location in the *S. purpuratus* histone repeat[6,22]. We have confirmed this location with a further S_1 mapping experiment (Fig. 2). For this experiment, the DNA probe was labelled by nick-translation, as the *Hae*II site which forms the internal protected end of the hybrid with the H4 mRNA could not be conveniently 5'-end labelled. Thus, in this experiment the protected DNA is compared with a heterologous size marker which can only be approximately related to the sequence. Even with this limitation, it is clear that the result shown in Fig. 2 places the H4 5' terminus adjacent to or within its cap box.

3' Termini

The sequence conservation in the homology blocks downstream from sea urchin histone genes is so great that their informational content cannot be doubted[9]. The relevant sequences for the h22 clone histone genes have now been determined and, as shown in Fig. 3, each gene fits with the pattern predicted by Busslinger *et al.*[9]. It was therefore of particular interest to determine the location of the 3'-mRNA termini in relation to these sequences. The location of the H3 3'-mRNA terminus was first mapped using S_1 nuclease and, as shown in Fig. 4, is about 169 nucleotides downstream from an internal *Hae*III site (at −113), which by comparison with the sequence (Fig. 3), places it within a few
Fig. 2 Autoradiogram of S_1 mapping of the H4 mRNA 5' terminus. A *Hind*III/*Hae*II fragment spanning the H4 5' terminus from 44 base pairs within the coding region[6] was labelled by a nick-translation procedure producing largely full-length DNA[35], as shown in lane 1. S_1 nuclease mapping was carried out as in Fig. 1*a* but using approximately 0.5 pmol of DNA probe. The protected DNA (lane 2) is about 106 nucleotides long by comparison with pBR322/*Hpa*II size markers[29] (lane 3), and this position is indicated on the sequence by an arrow. The regions of the cap box and Hogness box are indicated.

3′ termini

Fig. 3 Sequences downstream from histone gene termination codons of h22. Sequencing was carried out by chemical cleavage [9,15] from the indicated restriction sites. Sequences for the H1 and part of the H2A and H2B 3′ non-coding regions are in refs. 6 and 9. The approximate locations of the mRNA 3′ termini are indicated.

nucleotides downstream from the dyad symmetry element. The DNA probe in this and subsequent 3′-mapping experiments was labelled by nick-translation and, as in Fig. 4, compared with size markers which could then be related to the sequence (see Table 1 and Fig. 3). Although this procedure is liable to greater error than the direct sequence comparison used for the 5′ termini, all the 3′ mRNA termini map in a similar relative position just after the dyad symmetry. The region of these termini indicated in Fig. 3 is uncorrected for possible DNA overhangs. It is, however, no more than two nucleotides downstream from the corresponding location for the last detectable 3′ nucleotides in the *S. purpuratus* H3 and H2A mRNase determined by RNA sequencing (I. Sures, personal communication). The very last 3 nucleotides may, however, be the highly conserved sequence ACCA-OH as this also seems to be the sequence of the 3′-terminal oligonucleotide of the *L. pictus* H4 mRNA[36].

Discussion

We have shown that the mRNA termini coded by the principal embryonic histone repeat of *Psammechinus miliaris* are topologically related to partially conserved DNA sequence elements flanking the protein coding regions. The first in the direction of transcription is the Hogness box[10]; this is found in the consensus form (5′TATAAATA3′) in front of the H2A and H3 genes and only modified by one nucleotide in front of the H2B gene. Deformed versions of the sequence are also present in front of the H4 and H1 genes. The significance previously attached to this degenerate homology relies heavily on its rather constant proximity to mRNA precursor termini[10,12,14,23] and, in particular, to the fact that it lies in a similar relationship to the 5′ terminus of the adenovirus late transcription unit[24]. These observations, as well as the sequence similarity, have previously led to the suggestion that it may form part of an RNA polymerase II promoter functionally analogous to a Pribnow box in prokaryotes. The basis for this analogy, however, has recently proved rather limited. Several polymerase II-transcribed genes exist without a Hogness box in the sequence upstream from the cap sites[19], whereas a Pribnow box is always discernible in prokaryotic promoter regions[25].

Recent work in this laboratory has shown that deletion of the TATAAATA as well as some flanking sequences in front of the H2A reduces the level of H2A mRNA production only about fivefold when the mutated DNA is expressed following microinjection into *Xenopus* oocyte nuclei, whereas the deletion of a Pribnow box abolishes prokaryotic promoter function[4]. A potentially more revealing observation is that the absence of the 5′TATAAATA3′, whether natural[19] or of artificial[4] origin, leads to multiple cap sites, suggesting that the sequence may be a 'selector' instrumental in specifying a unique, or at least predominant cap site[4]. Although we have no direct evidence that this occurs as part of the initiation of a primary transcript in the histone system, there is mounting evidence for a 'cap-promoter' hypothesis[24,26]. Note also that prokaryotic as well as eukaryotic transcripts generally begin with a purine preceded and followed by a purine, with CAT being a favoured combination[27,29]; thus, there may be some selectivity at this level which is reflected in the 5′pyCATTCpu3′ homology near or at the *Psammechinus* histone mRNA 5′ termini. Moreover, Levy et al. have recently shown that an identical cap box lies close to the *S. purpuratus* H2B mRNA 5′ terminus[30].

The exact function of the conserved sequence blocks downstream from the sea urchin histone coding sequences is unknown. However, they share several features with typical prokaryotic terminator or attentuator sequences[25,31,32] as well as

Fig. 4 Autoradiogram of S₁ mapping of the H3 3′ terminus. The *Hae*III fragment used for sequencing the H3 3′ non-coding region (Fig. 3) was nick-translated and used for S₁ nuclease mapping of the H3 3′ terminus as in Fig. 2. The protected DNA (lane 1) is about 169 nucleotides long compared with known partial A cleavage fragments[15] (lane 2), and, therefore, maps the 3′terminus about 56 nucleotides downstream from the termination codon.

Table 1 S₁ nuclease mapping of h22 mRNA 3′ termini

mRNA	Location of 3′ end of DNA probe		Approximate length of protected DNA	Deduced location of 3′ mRNA terminus (see Fig. 3)
H4	*Hae*II	−25	71	46
H2B	*Mbo*II	−83	138	55
H3	*Hae*III	−113	169	56
H2A	*Xho*I	−184	240	56
H1	*Hae*III	−23	79	56

Restriction cut sites are as in ref. 5 and locations indicated are upstream from termination codons. Probes were labelled by nick-translation and mapping was carried out essentially as in Fig. 2 using either pBR322/*Hpa*II size markers (H4, H2B, H2A, H1) or a partial known sequence ladder (H3, Fig. 4).

with polymerase III terminator sequences[27]. Most striking is the GC-rich hyphenated dyad symmetry followed by a relatively AT-rich region. We do not know the mode of production of the mRNA 3' termini, but the fact that they map within or a few nucleotides downstream from this feature is consistent with a termination model.

If the sea urchin histone mRNA termini do normally arise through promotion of termination, one would not expect that RNA from spacer regions of the genes would be present in cells actively transcribing the h22-like genes, and so far we have failed to detect such RNA using spacer-specific cloned DNA probes. However, it is conceivable that the proposed termina-tion is regulated so that a normally negligible level of read-through could, in certain circumstances, become significant,. as is the case in prokaryotes[25,31,32]. This possibility could reconcile some of the conflicting evidence on the mode of transcription of these genes[7].

Search for radio emission from the young supernova remnants in NGC6946

M. P. Ulmer*, Patrick C. Crane†, Robert L. Brown† & J. M. van der Hulst‡

Although recent supernovae in our own Galaxy are among the brightest radio sources in the sky—particularly Cas A and the Crab Nebula (500-1,000 yr post-outburst)—the evolution of their radio emission from outburst to the present is, of course, unknown. Unless and until we have the opportunity to study a new galactic supernova, our information on the immediate post-outburst radio properties of supernova remnants must come from studies of identified supernovae in external galaxies. NGC6946 is one galaxy in which such a study is particularly favourable both because supernovae occur frequently in this galaxy—four supernovae have been identified since 1917—and because of its relative proximity. Two previous searches have failed to detect radio emission from these remnants[1,2]. However, the greater sensitivity presently available at radio wavelengths allows us not only to conduct a more sensitive search for these remnants but also to determine whether the radio emission has brightened since the last surveys ~ 5 yr ago.

In March 1979 we mapped NGC6946 with the VLA at 6 and 20 cm. For these observations we used 14 antennas which provided 91 baselines ranging in length from 50 m to 18 km; the resulting resolution was as high as 0.3 arc s at 6 cm and 0.8 arc s at 20 cm. We restricted the instrumental bandwidth to 12 MHz so as to obtain fields of view $\geqslant 10$ arc min at both wavelengths (FWHM). We first made a large but low resolution (4 arc s per cell) map of the entire region centred on the nucleus of NGC6946 to identify possible confusing field sources. From this map we subtracted the best fit to the central component and then made high resolution maps centred on the positions of each of the four supernova remnants[3]. We did not detect radio emission at any of these positions; our observational limits are summarised in Table 1. Excluded from this tabulation is a tentative 1969 supernova identification which was not confirmed; it does not appear on a list of recent extragalactic supernovae compiled by Sargent et al.[3].

Although no radio emission from the supernova remnants (SNRs) in NGC6946 was detected, our limits are, nevertheless, a factor ~5 lower than those obtained in 1971 at 20 cm with the WSRT[1] and they are a factor of more than 10 lower than the limit obtained at 11 and 3.7 cm in the 1975 NRAO inter-ferometer survey[2]. Moreover, if we adopt 7 Mpc as the distance to NGC6946 (ref. 4) (note that estimates of this distance range between 4.2 (ref. 5) and 10.5 Mpc (ref. 6)) we find that our limits on the 20 cm (1,400 MHz) monochromatic luminosity of the SNRs in NGC6946 are comparable with the present mono-chromatic luminosity of Cas A at this frequency (2.5×10^{18} W Hz^{-1}). To the extent, therefore, that Cas A is suitably representative of evolving Type II SNRs, we conclude that the peak radio luminosity must occur between 50 and 300 yr after the outburst.

That the flux density is not greatest at outburst is not surpris-ing in view of the large free-free optical depth of the remnant at early times ($\leqslant 10$ yr)[7]. However, a reliable determination of precisely when the radio emission should reach maximum intensity depends not only on the nebular parameters but also on the density of the ambient medium[7] and whether or not a pulsar contributes to the supply of relativistic particles within the remnant[8]. Hence, a full interpretation of our results depends critically on ancillary information particular to the supernova and its environment about which we have no specific knowledge. A few general remarks are necessary, however.

Assuming that the temperature in the expanding SNR envelope is ~10^4 K at the typical age of the historical remnants in NGC6946, $t \sim 10^9$ s, then the nebular envelope will still be

Table 1 Upper limits (3σ) to the radio emission from recent supernovae in NGC6946

				Flux density (mJy)		Luminosity $(10^{18}\text{W Hz}^{-1})$*

*Monochromatic luminosity.

optically thick to free–free absorption if

$$\left(\frac{M}{10M_0}\right)^2\left(\frac{v}{5{,}000\text{ km s}^{-1}}\right)^{-5} \geqslant 0.5$$

Adopting $M = 10M_0$ we can thus distinguish two cases: rapidly expanding remnants $v > 5{,}000$ m s^{-1}, and slowly expanding remnants, $v \leqslant 5{,}000$ km s^{-1}; the former will (now) be optically thin whereas the latter are still thick. Consider first the optically thick nebulae. In this case the expected radio flux density is $S = (\varepsilon_s/\kappa_{th})\Omega$ where ε_s is the synchrotron emissivity and κ_{th} is the thermal absorption coefficient. For a typical power law spectrum of relativistic electrons $N(E)\,dE = N_0 E^{-2.5}\,dE$ in the remnant which extends to energies as low as 10 meV, our 5-GHz observations impose the following constraint on a SNR expanding at 5,000 km s^{-1},

$$E_e < 1.0 \times 10^{43} B^{-7/4}\text{ erg}$$

where E_e is the total energy in relativistic electrons in the SNR and B(G) is the magnetic field. This inequality is illustrated in Fig. 1. Further, the synchrotron emission will be suppressed at 5 GHz by the Razin–Tsytovich effect unless $B > 9.2 \times 10^{-5}$ G; this limit is imposed by the condition that $\nu_R > 5$ GHz is also shown on Fig. 1.

Hence we conclude that if the historical SNRs in NGC6946 are slowly expanding at $v \leqslant 5{,}000$ km s^{-1}, then our observational limits require either (1) that the magnetic field in the remnants is $B < 9.2 \times 10^{-5}$ G, or (2) that the total energy in relativistic electrons in the remnants $E_e < 1.2 \times 10^{50}$ erg (that is less than 4% of the SNR kinetic energy).

Similar results are obtained for rapidly expanding, optically thin remnants. For example, if we adopt $v = 10{,}000$ km s^{-1} as an expansion velocity and carry out the same calculations as described above, the corresponding limits on E_e and B are

$$E_e < 5.5 \times 10^{42} B^{-7/4}\text{ erg}$$
$$B > 1.1 \times 10^{-5}\text{ G}$$

These results, while specific, are representative of the results obtained with any other reasonable choice of remnant parameters.

Of the two possible explanations for the low radio luminosity of the SNRs in NGC6946—that the total energy in relativistic electrons is $\leqslant 10\%$ of the SNR kinetic energy or the magnetic field is sufficiently low to cause the 5-GHz radio emission to suffer Razin–Tsytovich suppression—the weak magnetic field seems less likely to be correct because this requires such large departures from equipartition: the total magnetic field energy $< 10^{-9}$ of the SNR kinetic energy. Thus it seems that the young (<50 yr) SNRs in NGC6946 are not (yet) radio sources as luminous even as Cas A because they have not acquired (or generated) enough relativistic electrons. This in turn means either that newly formed pulsars require $\geqslant 50$ yr to begin producing copious quantities of energetic particles, or that relativistic electrons are accelerated in the expanding SNRs at a rate $\leqslant 10^{41}$ erg s^{-1}. Eventually, the way to distinguish between these latter two possibilities is to follow the detailed radio evolution of a historical extragalactic supernova remnant; at present, however, it seems far more profitable to direct efforts to a thorough elucidation of the energetics of the youngest galactic remnants[7,9].

If Razin–Tsytovich suppression is not important (see text), then the observational limits require the SNR to lie in the unshaded portion of this figure.

Possible existence and chemistry of ClO·O₂ in the stratosphere

Sheo S. Prasad

Jet Propulsion Laboratory, California Institute of Technology, 4800 Oak Grove Drive, Pasadena, California 91103

The possible existence and chemistry of asymmetric ClO·O₂ in the stratosphere could resolve the current apparent discrepancy between the observed steep but theoretically predicted much slower decrease of ClO mixing ratio with altitude below the peak. This conjecture follows from the recent finding[1] that possible formation of ClO·O₂ from ClO and O₂ may be the physical mechanism by which O₂ suppresses the quantum yields in chlorine photosensitized decomposition of ozone (refs 2, 3 and C. S. Lin, S. Jaffe and W. DeMore, unpublished results). In this letter it is suggested that introduction of ClO·O₂ in current photochemical models of the stratosphere could make the observed variability of ClO more understandable. It could also provide a possible mitigating influence on the present estimates of O₃ destruction from CFM consumption.

Formation of an asymmetric $ClO \cdot O_2$ complex might explain[1] the observed suppression of the quantum yield in chlorine photosensitized decomposition of ozone when O_2 is present (refs 2, 3 and Lin *et al.* unpublished results). An equilibrium constant $K_1 = k_{1f}/k_{1r} = 3.7 \times 10^{-19}$ cm^3 molecule^{-1} at 298 K was derived for the assumed reaction:

$$ClO + O_2 + M \underset{k_{1r}}{\overset{k_{1f}}{\rightleftharpoons}} ClO \cdot O_2 + M \qquad (1)$$
It was also shown that the potential reaction:

$$ClO \cdot O_2 + Cl \to Cl_2O + O_2 \qquad (2)$$
provided a viable explanation for the very low quantum yield (<2) observed by Wongdontri-Stuper *et al.*[3] when the ozone partial pressure was very small (a few millitorr) in their experiments. We conjecture that $ClO \cdot O_2$ complex may exist in significant quantities in the stratosphere, and that the following reactions of $ClO \cdot O_2$ with O, NO, and NO_2 can be hypothesized:

$$ClO \cdot O_2 + O \to ClOO + O_2 \qquad (3a)$$

$$ClO \cdot O_2 + NO \to ClONO + O_2 \qquad (4)$$

$$ClO \cdot O_2 + NO_2 \to ClONO_2 + O_2 \qquad (5)$$
Switching reactions similar to reactions (2), (4) and (5) are common with cluster ions[4], and it may be that neutral clusters (such as $ClO \cdot O_2$) share with their ionic analogue a tendency to undergo these reactions. The possible existence of $ClO \cdot O_2$ in the stratosphere provides a potential explanation for the current discrepancy between *in situ* measurements[5,6] and theoretical predictions[7] of the stratospheric ClO mixing ratio at lower altitudes.

Figure 1 illustrates the present discrepancy between observed and calculated profiles of ClO mixing ratios. Observed and theoretical values of ClO mixing ratios can be matched in the 35–40 km region by suitable choices of ClX and H$_2$O ratios. The values of ClX needed for this match result in satisfactory concentrations for most other related species—Cl for instance. This agreement in the 35–40 km altitude region is not matched at altitudes below about 35 km. The rapid decrease with altitude in the observed n(ClO) mixing ratio is a problem which has been attributed to experimental errors and/or some omission in the theoretical chemical model.

To appreciate the possibility of resolving this problem by invoking our $ClO \cdot O_2$ hypothesis, note that diurnally averaged models may be almost completely insensitive to the presence of $ClO \cdot O_2$. This is a result of the following reactions:

$$ClO \cdot O_2 \overset{O}{\to} ClOO \overset{M}{\to} Cl + O_2 \qquad (6)$$

$$ClO \cdot O_2 \overset{NO}{\longrightarrow} ClONO \begin{cases} \overset{h\nu}{\longrightarrow} Cl + NO_2 & (7) \\ \overset{h\nu}{\longrightarrow} ClO \overset{NO}{\longrightarrow} Cl + NO_2 & (8) \\ \overset{h\nu}{\longrightarrow} NOCl \overset{h\nu}{\longrightarrow} Cl + NO & (9) \end{cases}$$
in which the end products of the possible reactions of $ClO \cdot O_2$ with O and NO in sunlight are the same as those of reactions between ClO and O and NO. Because of the possible occurrence
Fig. 1 Comparison between *in situ* measurements of stratospheric ClO mixing ratio and theoretical model predictions. Experimental data (●) are from Anderson *et al.*[6]. Theoretical profile, due to Logan *et al.*[7] (solid line) corresponds to spring/autumn conditions at 30°N. The rapid decline of measured ClO mixing ratio with decreasing altitude seen here is also evident in additional examples of *in situ* measurements and theoretical calculations presented by Anderson *et al.*[6].

of reaction (5), the predicted n(ClONO$_2$) profile may also remain virtually unaffected. Thus, diurnally averaged models with and without $ClO \cdot O_2$ would be almost identical, except that n(ClO)+n(ClO·O$_2$) in the former case would equal n(ClO) in the latter case. The measurements of Anderson *et al.*[5,6], however, would discriminate between ClO and $ClO \cdot O_2$ because atomic chlorine may not be produced in reactions of $ClO \cdot O_2$ with NO. Thus, while ClO is measured by Anderson *et al.*[5,6], $ClO \cdot O_2$ would be undetected. In other words, the difference between n(ClO) observed by Anderson *et al.*[5,6], and that calculated on the basis of current photochemical models (see ref. 7) may possibly be equal to the amount of n(ClO·O$_2$) present in the stratosphere. Possible stratospheric n(ClO·O$_2$)/n(ClO) ratios estimated on the basis of above considerations and data presented in Fig. 1 are shown in Table 1.

Assuming that stratospheric $ClO \cdot O_2$ is quite loosely bound, collisional dissociation of $ClO \cdot O_2$, that is, $ClO \cdot O_2 + M \to ClO + O_2 + M$, is likely to be faster than photodissociation, so that

$$n(ClO \cdot O_2)/n(ClO) = K_1 n(O_2) \qquad (10)$$

should be a good first-order approximation. Values of K_1 calculated on this basis are also given in Table 1. A plot of $\ln K_1$ against $1/T$ is shown in Fig. 2. Error bars attached to the stratospheric data points were determined by considering: (1) ±35% uncertainty in the measured ClO mixing ratios; (2) ClO measurements on 11/78, 12/77, 10/77, 9/77 and 12/76 and corresponding theoretical calculations of Logan *et al.* using only 5.5 p.p.m. of H$_2$O as shown in Fig. 8 of ref. 6; (3) uncertainties in the assumed background model atmosphere; and (4) uncertainties in stratospheric n(OH) due to possible pressure dependence of the rate coefficient for the reaction $HO_2 + OH \to H_2O + O_2$ as recently discussed by Turco *et al.*[8]. Uncertainty in $\ln K_1$ obtained from a previous analysis[1] of the laboratory data of

† Data from Fig. 1.
Fig. 2 A $\ln(K_1)$ plotted against $1,000/T$. The point marked X is from an analysis of the experimental data of Wongdontri-Stuper *et al.* Remaining data points (●) are from an analysis of stratospheric measurements as explained in the text. The straight line represents a least square fit to the data points.

Wongdontri-Stuper *et al.* arises from the uncertainty in the rate coefficient of the overall reaction of $ClO \cdot O_2$ with ClO. The error bar attached to this $\ln K_1$ reflects an arbitrary, but reasonable, conjecture that the abovementioned rate coefficient may be either a factor of two larger or smaller than the nominal value used previously[1]. A least square analysis yields $K_1(T) = 3.28 \times 10^{-24} \exp(3,470/T)$ cm^3 molecule^{-1}, with $K_1(T) = 7.28 \times 10^{-24} \exp(3,464/T)$ and $1.16 \times 10^{-24} \exp(3,549/T)$ cm^3 molecule^{-1} as the upper and lower bounds. The main points are: (1) K_1 obtained from two entirely independent considerations— analysis of laboratory data and stratospheric measurements—lie very close on a single plot, and (2) the slope of this $\ln K$ against $1/T$ plot is as expected by analogy with other loosely bound species, such as $ClOO$. These are not unlikely to be chance coincidences. These two points suggest that the possible existence of $ClO \cdot O_2$ complex in laboratory experimental situations can be extrapolated to a possible existence of $ClO \cdot O_2$ in the stratosphere; in quantities sufficient to resolve the current discrepancy between the measurements of Anderson *et al.*[5,6] and current theoretical models of stratospheric ClO mixing ratios.

As pointed out by Logan *et al.*[7], "The observed variability of ClO is puzzling, and raises the possibility of a major gap in our description of the chlorine cycle". Our conjecture is that the potential existence of $ClO \cdot O_2$ in the stratosphere bridges this gap. We have already seen how $ClO \cdot O_2$ complex may possibly explain the current discrepancy between observed and theoretically predicted altitude profiles of the ClO mixing ratio. Rocket measurements[9] of stratospheric T and n indicate that local changes in these quantities tend to reinforce each other's effect on the ratio $n(ClO \cdot O_2)/n(ClO)$ via equation (10), and a day-to-day variability of this ratio by as much as 50–60% is quite possible even at 30 km from this cause alone. Thus, the introduction of $ClO \cdot O_2$ could make the observed variability of ClO more understandable. In addition, it is possible that the reaction:

$$ClO \cdot O_2 + O \rightarrow OClO + O_2 \qquad (3b)$$
occurs. Photodissociation of $OClO$, that is, $OClO + h\nu \rightarrow O + ClO$, results in regeneration of odd oxygen. The fraction of $ClO \cdot O_2$ which reacts with O via reaction (3b) to produce $OClO$ does not immediately destroy odd oxygen. Consequently, $ClO \cdot O_2$ in the stratosphere and reaction (3b) together may have a mitigating influence on the present estimates of ozone reduction due to chlorofluoromethane consumption. Finally, a direct experimental verification of possible $ClO \cdot O_2$ formation from ClO and O_2 would be very useful.

Observation of static electromagnetic angular momentum *in vacuo*

G. M. Graham & D. G. Lahoz

Department of Physics, University of Toronto,
Toronto, Canada M5S 1A7

Our programme of measurement of forces related to electromagnetic momentum at low frequencies in matter has culminated in the first direct observation of free electromagnetic angular momentum created by quasistatic and independent electromagnetic fields E and B in the vacuum gap of a cylindrical capacitor. A resonant suspension is used to detect its motion. The observed changes in angular momentum agree with the classical theory within the error of ~20%. This implies that the vacuum is the seat of something in motion whenever static fields are set up with non-vanishing Poynting vector, as Maxwell and Poynting foresaw.

In establishing the electromagnetic nature of light, Maxwell[1] opposed Weber's "action at a distance" with his "dynamical" model of a vacuum with hidden matter in motion. His ideas were expanded by Poynting through the energy-flux theorem, but relativity theory initially dealt them a blow. However, despite Einstein's explicit reconciliation with the aether[2] there is currently some doubt about Maxwell's medium. It was in a relativistic context that Minkowski[3] found, as a purely mathematical consequence of Maxwell's equations, that the Lorentz force density could be exactly expressed as the divergence of Maxwell's tensor *in vacuo*, T_{vac}, decreased by the rate of change of Poynting's vector:

$$\rho \, \mathbf{E} + \mu_0 \mathbf{J} \times \mathbf{H} = \nabla \cdot T_{vac} - \frac{\partial}{\partial t} \, \varepsilon_0 \mu_0 \mathbf{E} \times \mathbf{H} \qquad (1)$$

According to Maxwell–Poynting ideas, the last (Minkowski's) term in equation (1) can be interpreted as a local reaction force acting on charges and currents when the vacuum surrounding them is loaded with electromagnetic momentum. Einstein and Laub[4] observed that if equation (1) is integrated to all space, the term $\nabla \cdot T_{vac}$ generates a vanishing surface integral and therefore the system of all Lorentz forces in the Universe needs to be supplemented with the quantity $\int_\infty \varepsilon_0 \mu_0 \, \partial/\partial t \mathbf{E} \times \mathbf{H} \, dv$ to preserve Newton's third law. The opposite of this last vector is usually interpreted as the net unlocalized reaction on charges and currents due to radiation fields but, classically at least, it also represents a real reaction force even with induction fields.

We have made, to our knowledge, the first direct observation of the Minkowski term with induction fields $\mathbf{E}$ and $\mathbf{B}$, which are confined to a small volume so that the local nature of the vacuum reaction term has also been demonstrated. The experiment consists of measurement of the axial torque on a cylindrical capacitor and its radial leads, located in an axial magnetic field. Thus $\mathbf{E} \times \mathbf{H}$ is azimuthal inside the vacuum gap of the capacitor. The details of the capacitor and its mounting on a torsion oscillator are shown in Fig. 1. The capacitor and its leads form a rigid and nearly closed electrical loop. The magnetic field and the capacitor voltage are time varied so that one Fourier component of their product is locked to the resonant frequency

of the mechanical system, which is of sufficiently high $Q(>10^5)$ to yield a measurable oscillation amplitude when viewed by a μ-radian sensitive optical lever. Knowledge of the resonant amplitude and frequency, moment of inertia and free decay time (with $\mathbf{E} = 0$) yield the driving torque. The suspension system is located in the vacuum interspace of a liquid helium Dewar. The magnetic field, uniform to $\sim 2\%$, is supplied by a superconducting solenoid.

This technique is an extension of our previous work[5] on electromagnetic forces in material media, with dielectric or magnetic material in the capacitor. In those experiments, the magnetic field was held fixed and the voltage was impressed at the resonant frequency. This resulted in a large resonant noise due to elestrostatic forces (at the second harmonic) which coupled back in some degree at the resonant frequency. The present experiment was made possible by detuning the voltage from resonance by ~ 1 Hz, using as a source the output of a high stability oscillator. This signal ($\nu = 243.31$ Hz) was electronically multiplied by the signal ($\nu = 242.18$ Hz) from the slave oscillator phase locked to the resonant system by the optical lever, so that sum and difference frequencies were generated. After low pass filtering, the difference signal was used to drive the magnet. In this way, one component of the product $\mathbf{EH}$ was at the resonance but $(\mathbf{E}^2)^{1/2}$ was not. The various phase shifts in the circuitry were carefully nulled. A calibrated pick-up coil provided absolute measurement of $\mathbf{H}$. The apparatus permitted reasonable measurements of torque over a range of about a factor of 3 in both $\mathbf{E}$ and $\mu_0\mathbf{H}$, up to maximum amplitudes of 2×10^6 V m^{-1} and 0.3 T respectively.

Measured torques are compared in Table 1 with calculated torques acting on the suspension which arise entirely from the net Lorentz force on the current I in the radial leads which charges the vacuum component of the suspended capacitor, that is, a torque $I\mu_0 H(a^2 - b^2)/2$, where a and b are the outer and inner radii of the capacitor cylinders (~ 5.5 and 4.5 mm). Here I has been corrected for the known stray capacitance to earth

Table 1 Calculated and observed torque amplitude for typical field amplitudes (the electric field is given at the inner electrode)

E_0 (MV m^{-1})	B_0 (T)	$T_{0,\text{calc}}$ (pN m)	$T_{0,\text{obs}}$ (pN m)
0.58	0.13	2.0	1.8
0.64	0.22	3.5	4.4
1.3	0.22	7.1	8.5
1.7	0.19	7.9	8.7
2.3	0.22	12.4	17.0

external to the suspension (~ 1 pF effective) and for the fraction of conduction current which corresponds to polarization current in the dielectric end plates, as that part corresponds to a closed loop of current contributing no torque. Thus I corresponds to charging a pure vacuum capacitance C_0 only. C_0 was calculated from the geometry (4.7 pF) and also estimated by measuring the effect of removing one end plate (4.9 pF). The error in the calculated torque is mainly due to the uncertainty in the corrections for stray capacitance. It is estimated to be $\sim 10\%$. The systematic trend in the ratio of T_{calc} to T_{obs} can be understood in terms of a small, amplitude dependent, non-linearity in the equation of motion, due to magnetic field dependence of the damping, which results in imperfect cancellation of the resonant noise[5] at high fields. Consequently, the tabulated discrepancies are within an estimated total error of $\sim 20\%$.

Although this result is to be expected by classical electromagnetism, it leads inexorably to the acceptance of the physical reality of the Poynting vector, even though $\mathbf{E}$ and $\mathbf{H}$ arise from independent sources. This can be seen by seeking the system on which the third law reaction torque must act. It can be neither the external electrical circuit, as the loop is essentially closed within the suspension, nor in the magnet, which, as a coil, cannot receive an axial torque (force parallel to its own current). For angular momentum conservation, the loop is an isolated system and the reaction torque can only be considered as a change in electromagnetic angular momentum carried by the fields themselves in the region of their co-existence, that is, within the vacuum gap of the capacitor. As $I = C_0 dV/dt$, the calculated torque is exactly equal to the volume integral of $\mathbf{r} \times \partial(\mathbf{E} \times \mathbf{H})/\partial t c^2$, so that the complete reaction is accounted for by the assignment of a real angular momentum density to $\mathbf{r} \times (\mathbf{E} \times \mathbf{H})c^2$ (ref. 5).

It is remarkable that no known 'particle' can be identified as the agent of the observed electromagnetic angular momentum in exchange with the mechanical detector. However, this does not imply that a new entity has to be introduced, because the concept of energy-momentum carried by macroscopically quasistatic electromagnetic field is already contained in Maxwell's equations. According to these, and as directly implied by our experimental result, permanent magnets and electrets can be used to build a flywheel of electromagnetic energy steadily flowing in circles in the vacuum gap of a capacitor as if Maxwell's medium were endowed with a property corresponding to superfluidity. The certainly new insight is that the quasistatic Maxwell's field is not merely an unobservable medium of interaction between matter and matter: it has in fact the mechanical properties postulated by Maxwell, in contradistinction to any "action at a distance" theory.

This experiment is continuing and a complete report will be published elsewhere.

Diphosphine is an intermediate in the photolysis of phosphine to phosphorus and hydrogen

James P. Ferris & Robert Benson

Department of Chemistry, Rensselaer Polytechnic Institute, Troy, New York 12181

Phosphine (PH_3) has recently been identified as a constituent of the atmospheres of Jupiter and Saturn[1-3]. It is probably formed in the hot depths of the atmospheres of these planets and is carried to the upper levels by atmospheric turbulence. The red colorations in the atmosphere and Great Red Spot of Jupiter may be due to the photolysis of the PH_3 in the upper atmosphere to red phosphorus (P_4) (ref. 4). We initiated an investigation of PH_3 photolysis because of its potential significance in the atmospheric chemistry of Jupiter[4-6]. We report here that P_2H_4 is the initial product of PH_3 photolysis and that it is the principal intermediate in the formation of red phosphorus. These findings require substantial revision of the previously accepted mechanism for PH_3 photolysis[6-8].

Photolysis of PH_3 (87 torr) at room temperature with a 206.2 nm light source[9] gave a product with UV absorption extending from 270 nm to below 200 nm (Fig. 1). This compound was identified as P_2H_4 by comparison of its IR[10] and UV spectra and gas chromatographic retention time (on a 6 ft OV-1 column operating at 30 °C) with that of an authentic sample[11]. No products, other than hydrogen and PH_3, were detected by gas chromatography. The yield of P_2H_4 as a function of illumination time increases to a maximum and then decreases to about 20% of its maximum value (Fig. 2). (We cannot explain the maximum in the formation of P_2H_4. This reproducible finding is not due to P_2H_4 photolysis because PH_3 absorbs more than 97% of the light at 206.2 nm when the concentration of P_2H_4 reaches a maximum. Consequently little if any P_2H_4 photolysis will be occurring. This same variation in N_2H_4 yield is

observed when NH_3 is photolysed. The yield of N_2H_4 first increases and then decreases with irradiation time[12]. The yield of P_4 levels off with time in Fig. 2 because the 206.2 nm light intensity is attenuated by the formation of a P_4 layer on the cell window.) This is due in part to the build-up of P_4 on the window of the reaction cell which reduces the intensity of the 206 nm light. P_2H_4 may not have been discovered previously as a photoproduct because product analysis was performed after prolonged irradiation[7].
Fig. 2 Yields of P_4 (▲) and P_2H_4 (●) as a function of time of irradiation. Photolysis of 87 torr PH_3 at room temperature in a 10 cm quartz cell (capacity ~75 cm^3) using an iodine lamp with principal emission at 206.2nm. Shorter wavelengths were removed with a 1cm quartz cell containing distilled water.

In the previous mechanisms for the photolysis of PH_3 to P_4 (reactions (1)–(6)) a reaction sequence involving disproportionation of the initially formed PH_2 was proposed (reaction (2))[7,8]. Our discovery of P_2H_4 as a photoproduct suggests an alternative mechanism which includes the formation of P_2H_4 from PH_2 (reaction (8)).

$$P_2H_2 \rightarrow P_2 + H_2 \tag{14}$$

Fig. 1 UV spectrum of P_2H_4 measured in a 10 cm cell with Cary 219 spectrophotometer.
If disproportionation of PH_2 (reaction (2)) is an important pathway in P_4 formation then P_4 will be formed along with P_2H_4 (reaction (8)) at very short irradiation times while in the absence of disproportionation P_4 formation will be negligible. It can be shown that $k_2/k_8 = \lim_{t \to 0}(4n_{P_4}/n_{P_2H_4})$ and a plot of $n_{P_4}/n_{P_2H_4}$ against time of irradiation will go through the origin if there is no
Fig. 3 Ratio $n_{P_4}/n_{P_2H_4}$ versus time of irradiation.

disproportionation of PH_2. (This expression is derived from equations (1)–(8) assuming PH, PH_2 and P_2 are formed in small steady state amounts. Equations (9)–(14) are not included because they apply only at longer irradiation times.) The data of Fig. 3 prove that disproportionation is a minor reaction pathway, a finding which establishes that P_2H_4 is the principal intermediate in the photoconversion of PH_3 to P_4.

The quantum yield for PH_3 (ϕPH_3) loss was determined by both the sum of $4\phi P_4$ and $2 \phi P_2H_4$ and the sum of the $2/3 \phi H_2$ and $4/3 \phi P_2H_4$. (P_2H_4 was determined by its UV absorbance at 235 or 250 nm; H_2 was determined using a thermal conductivity gas chromatograph on a 6 ft molecular sieve 5 Å column with Ar as carrier gas; P_4 was determined colorimetrically as described in ref. 13; actinometry was performed by photolysis of 100 torr of NH_3 in a 10 cm cell ($\phi = 0.31^{14}$). ϕPH_3 is ~ 0.7 by both methods for long irradiation times as reported previously[7] but is greater than 1 at short irradiation times. That the ϕPH_3 is >1 suggests that hydrogen abstraction from PH_3 (reaction (7)) is significant in the conversion of PH_3 to PH_2 (ref. 15). The conversion of P_2H_4 to P_4 may proceed by several pathways (equations (9)–(14), (4)) suggested by analogy with conversion of NH_2NH_2 to N_2 (refs 16, 17). The data presented here establish that P_2H_4 is formed from PH_3, using light of 160–210 nm (ref. 18), by reactions (1), (7) and (8). The detection of P_2H_4 in these studies suggests that it is a likely consitituent of the atmospheres of the jovian planets which may be detected by Earth-based IR spectroscopy or during NASA's Galileo mission to Jupiter.

Angiosperm fossils in supposed Jurassic volcanogenic shales, Antarctica

T. H. Jefferson

Department of Geology, Downing Street, University of Cambridge, Cambridge CB2 3EQ, UK
and
British Antarctic Survey, Natural Environment Research Council, Madingley Road, Cambridge CB3 0ET, UK

During palaeobotanical studies in the Antarctic Peninsula in February 1979, late Cretaceous or younger fossil angiosperm leaves were found within volcaniclastic rocks widely believed to be of late Jurassic age[1]. Although poorly preserved, these fossils are of great stratigraphical importance. They occur at Cape Alexandra, Adelaide Island (Fig. 1), in rocks correlated with the lowest part of the exposed succession (Sloman Glacier succession[1]). The fossils were found less than 10 km from the type locality for this succession at the head of Sloman Glacier (Fig. 1). However, towards the northern end of the island at Mount Bouvier (Fig. 1), ammonites and bivalves indicate that supposedly equivalent rocks[1] are of Upper Jurassic age[2]. This intensive study of a very small part of the succession indicates that the volcanic history of Adelaide Island is much more complicated than was previously suggested by reconnaissance mapping.

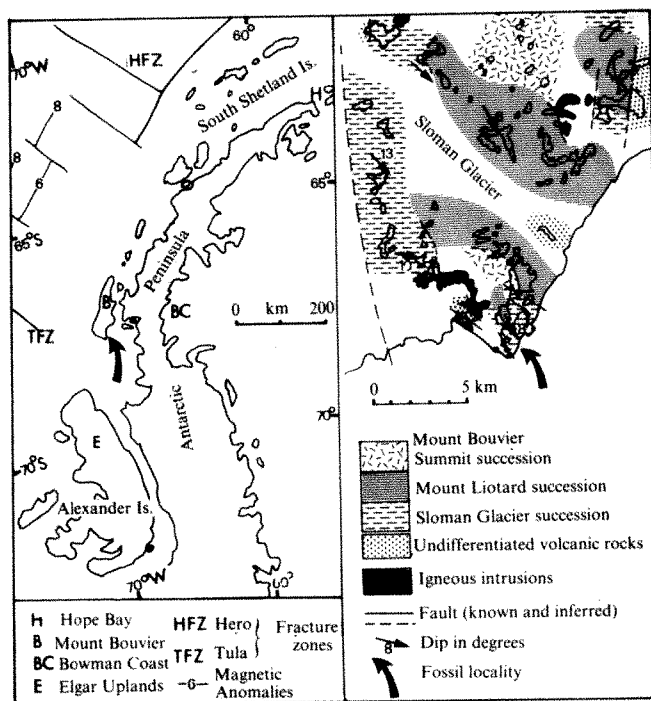
The leaves were found 10 m above the lowest stratigraphical horizon exposed at Cape Alexandra, in a succession of volcanic and volcaniclastic rocks which are at least 1,050 m thick. Nineteen specimens of pyritized impressions in a highly indurated black shale were collected. The leaves are open veined, without clearly defined margins. In several specimens there is a marginal zone of intensely pyritized material which


Fig. 1 *a*, A map of the Antarctic Peninsula showing the position of localities mentioned in the text. *b*, Geological map of the Cape Alexandra area, southeastern Adelaide Island (after Dewar[1], Fig. 5).

probably represents the decayed lamina edge. Two nearly whole, narrow ovate[3] leaves were recovered, the smaller of which is 7.6 × 4.2 cm (Fig. 2a), and the larger 8.0 × 4.1 cm (Fig. 2b). Mid-veins are straight, up to 1.3 mm in width (Fig. 2c) and taper towards the apex. Secondary veins are opposite to sub-opposite, arising at intervals of 7–9.5 mm near leaf bases and 6–7.5 mm at apices. They arise at 25°–45° from the mid-vein, angles at apices being up to 7° less than at bases. In two cases the basal secondary veins bifurcate (Fig. 2a, b). No tertiary veins or cuticles are preserved.

Preservation of the leaves is too poor to permit certain identification. However, the leaves bear a close resemblance to those found in volcanic rocks in the Elgar Uplands of Alexander Island[4], and to beech-like leaves in the Tertiary plant beds of the South Shetland Islands[5]. The leaves from the Elgar Uplands occur in rocks correlated lithologically with tuffs dated by K–Ar methods at 70 Myr (ref. 6). However, more extensive work on lavas interbedded with these tuffs gives K–Ar dates ranging from 41 to 63 Myr (R. J. Pankhurst, personal communication). Only one of the fossil floras from the South Shetland Islands has been described. Its age was assessed as Miocene[5], but preliminary K–Ar dating of associated lavas, by Pankhurst, suggests that an early Tertiary age is more likely.

Very few palynomorphs have been recovered using bulk HF techniques on two separate samples. Those found are highly carbonized, most are fragmentary and numbers are insufficient for positive identification. However, the recovered pollen grains which are complete have smooth exines. Two possess six colpi and are probably related to the form-genus *Psilastephanocol-pites*[7] (Fig. 3a, b). One has three colpi and is probably related to the form-genus *Psilatricolpites*[8] (Fig. 3c). Pollen grain fragments with a reticulate sculpture were also recovered (Fig. 3d). These forms are undoubtedly angiospermid. Further work is planned both on existing samples and on material to be collected during the 1979–80 field season.

Also found at Cape Alexandra were numerous compressed tree trunks and/or branches. These are all highly carbonized and no cellular details remain. Their size (up to 3 m in length) indicates that the arborescent vegetation was not in a dwarf or shrub form. Furthermore, the size of the leaves, and of those
from the Elgar Uplands[4], suggests a temperate climate for the southern Antarctic Peninsula at this time.

Although Cretaceous and Tertiary calc-alkaline volcanic rocks occur in the northern Antarctic Peninsula area, principally the South Shetland Islands[9,10], and in Alexander Island[11], evidence for post-Jurassic volcanism in the central part of the peninsula is at present very tenuous. Altered volcanic and volcaniclastic rocks throughout the Antarctic Peninsula have almost always been assigned an Upper Jurassic age[12], or referred to the 'Upper Jurassic Volcanic Group'[13,14]. This is on the basis of lithological similarity to rocks at Hope Bay (Fig. 1) overlying plant beds of supposed Middle Jurassic age[15]. The extension of the volcanic history of the Antarctic Peninsula through Upper Cretaceous and into Middle Tertiary time has been suggested previously. Taylor *et al.*[3], considered that rocks within the 'Upper Jurassic Volcanic Group' probably represent a much greater time period and Thomson[16] redefined the group as the Antarctic Peninsula Volcanic Group, a name which avoids time constraints. The discovery of the fossil leaves is the first direct evidence from the central Antarctic Peninsula area to demonstrate conclusively that volcanism continued well beyond the late Jurassic into Cretaceous and probably Tertiary times.
Fig. 3 Carbonized palynomorphs from Cape Alexandra, Adelaide Island.

Magnetic anomalies[17] indicate that subduction of the south-east Pacific plate under the Antarctic Peninsula between the Hero and Tula fracture zones (Fig. 1) continued until at least the Oligocene. This would be compatible with the probable continuous igneous activity on the Bowman Coast from early Jurassic to middle Tertiary times[18] and with the occurrence of angiosperm fossils within a volcaniclastic sequence on southern Adelaide Island.

Biotin and the sudden infant death syndrome

A. R. Johnson & R. L. Hood

CSIRO Division of Food Research, PO Box 52, North Ryde 2113, Sydney, Australia

J. L. Emery

Children's Hospital, Sheffield, UK

A diet which is marginally deficient in the vitamin biotin may cause sudden unexpected death of young broiler chickens when they are exposed to stress[1,2]. Chickens affected with this disorder have low levels of biotin in their livers. In conditions of biotin insufficiency, we postulate that a similar disorder, triggered by mild stress, may occur in the human infant. We have now used a radiochemical technique to measure the biotin content of 204 livers obtained from infants at autopsy. The levels of biotin in the livers of infants who had died of sudden infant death syndrome (SIDS; cot death) were significantly lower than those in livers of infants of similar age, who had died of explicable causes. These findings support an association of biotin with SIDS.

The stress, which precipitates death in chickens, need only be very mild; for example, disturbance and removal of their food at 2.30 a.m. resulted in chickens being dead, or almost dead by 8.00 a.m. Death occurred quietly with no signs of a struggle. This disorder is known as the fatty liver and kidney syndrome and often affects the largest chickens in a flock. When the birds' diet was supplemented with biotin the disorder was eliminated. In this disorder there are no symptoms of classical biotin deficiency, such as poor conversion of feed, dermatitis or other skin disorders. The birds were hypoglycaemic and death results from hypoglycaemic coma due to a reduction in the activity of the biotin-dependent enzyme pyruvate carboxylase[2]. This is a key enzyme in the gluconeogenic pathway which is responsible for the maintenance of blood glucose levels. When dietary biotin levels are marginal the pathway can synthesise sufficient glucose for the normal needs of a chicken but is unable to supply the amount required when the bird is challenged by a stress. We have suggested that stress-induced deaths may occur in animals of other species[2,3] including human infants[4] when their diets are marginally deficient in biotin. In a preliminary communication it was reported that biotin levels in the livers of infants who had died of SIDS were statistically lower than those in the livers of infants who had died of explicable causes[4].

In studies of SIDS it is essential to have a valid and consistent classification of the cause of death in infants[5]. In the present study, the classification of the cause of death was made (by J.L.E.) with no prior knowledge of the biotin content of the livers. The system of classification[6] is:

(A) Children with gross congenital deformities.

(B) Children with definite and severe disease such as would normally claim hospital admission and from which they could have died.

(C) Children with a mild disease which is of itself insufficient to explain death adequately.

(D) Children with no definite diagnosable disease to account for death, even though there may be evidence that the child may have been unwell at the time of death.

Infants whose cause of death was classified in group C or D are deemed to have died of SIDS.

In the adult, biotin can be derived from both the diet and synthesis by bacteria in the gastrointestinal tract. The contribution, if any, of intestinally synthesised biotin to the overall biotin supply is not known and as a result there are no definite recommended dietary allowances for biotin[7]. In the infant some weeks are required for a mixed population of gut microflora to develop and the increased biotin levels in infants over 1 week of age are probably derived from the diet alone until the mixed population becomes established. The biotin levels in the livers of stillborn infants or infants who died within 1 week post-partum were significantly ($P<0.001$) lower than those in livers of infants surviving more than 1 week (Table 1). The low levels in the newborn infants reflect the transfer of biotin from the mother through the placenta to the fetus.

The peak incidence of SIDS occurs at 3–4 months post-partum. In this study infants who had died between 1 and 52 weeks of life were treated as one group (Table 1). It was interesting to note that there was only one infant whose death was classified as group D. The remainder of SIDS victims were in category C; that is, there was some evidence of a disease which under normal circumstances would not cause death but would almost certainly impose an additional stress on an infant.

The median biotin levels in the livers of infants who died from SIDS between 1 and 52 weeks of life were significantly ($P<0.02$) lower than those of infants who died from explicable causes. The infants in groups A and B cannot be considered as normal controls. However, the impossibility of obtaining biotin levels from healthy infants makes this comparison the only one possible. Intermediate levels of biotin were found in the livers of infants who had died after 52 weeks of life. No conclusions can be drawn from this as the majority of infants had diseases of long standing.

It has been reported[8] in the UK that "cot death is commoner among bottle-fed babies even when the measure is only taken from records of feeding in the first few days[9]: breast feeding gives some protection". It was difficult to obtain reliable and objective information on the duration of breast feeding, but the majority of SIDS cases investigated in this study had been fed infant formulations at the time of death. If biotin is involved in SIDS it may be related to a difference between the available biotin content of breast milk and of infant formulations. A related paper[10] demonstrates that a considerable loss of biotin occurs during the manufacture of certain infant formulations.

There are three observations that indicate that biotin deficiency may be implicated in SIDS. First, there is unequivocal evidence of stress-induced sudden death in young chickens whose diet is marginally deficient in biotin. Second, the biotin levels in the livers of SIDS victims are lower than those in the livers of infants whose deaths were explicable. Third, biotin is

Table 1 Median values of the biotin content of infant livers

Age at death and SIDS classification	n	Liver biotin ($ng\, g^{-1}$)	95% Confidence limits of the median lower	upper
Stillborn and less than 1 week	69	249	222	307
1–52 weeks; groups A and B	57	419	368	462
1–52 weeks; groups C and D	35	336	277	356
>52 weeks	43	344	321	399

The biotin contents of the infant livers were assayed using the radiochemical method of Hood[11,12], with no prior knowledge of the cause of death at the time of analysis. Livers obtained at autopsy were supplied by the Children's Hospital, Sheffield. Following autopsy, the samples were frozen and flown to Sydney while still frozen. A test of skewness on the data for groups A and B and groups C and D indicated that the distribution of biotin levels were skewed ($P<0.05$). Therefore, a statistical test was used that did not assume the distributions were normal. It is a test of the null hypothesis that within each experiment the median of each group is the same. The levels of biotin were replaced by ranks and then the ranks of those observations in one treatment group were summed within each experiment. This provided a Wilcoxan rank sum statistic separately for each experiment. These values were then added. The sampling distribution for this sum was generated from 10,000 simulated experiments.

lost during the processing of some infant formulations[10], thus some bottle-fed infants may be receiving a diet marginally deficient in biotin.

The findings do not suggest that SIDS results from biotin deficiency alone, but, by analogy with chickens, we postulate that biotin insufficiency may leave the infant in a condition in which SIDS can be triggered by mild stress, for example infection, a missed meal, excessive heat or cold, or a changed environment. The evidence to date is circumstantial and it would be difficult to provide 'unequivocal proof' linking biotin, or for that matter any nutrient, with SIDS because of the difficulties in undertaking biochemical studies with experimental and control subjects.

Epidemiological techniques will have to be used and if our recommendation to supplement infant formulas with biotin[10] is implemented, the subsequent trends in the incidence of SIDS may enable the existence of any association to be evaluated more effectively.

The role of gastropod pedal mucus in locomotion

Mark Denny

Department of Zoology, University of British Columbia, Vancouver, B.C., Canada V6T 1W5

Gastropods move using a single appendage—the foot. For many gastropods the power for locomotion is provided by muscular waves moving along the ventral surface of the foot[1-3], the force of these waves being coupled to the substratum by a thin layer of pedal mucus. This mucus acts as a glue, allowing the animal to adhere to the substratum on which it crawls[2,3]. This adhesive ability is advantageous, particularly to animals (such as limpets and certain snails) which live in intertidal or arboreal habitats where the forces of waves and gravity must be resisted while the animal forages. However, the adhesiveness of the pedal mucus presents the animal with a problem. How can an animal with only one foot walk on glue? This question was studied using as an example the terrestrial pulmonate slug, *Ariolimax columbianus*, and locomotion is found to depend on the unusual mechanical properties of the pedal mucus.

The pedal mucus of *A. columbianus* is 96–97% water and dissolved salts[4]. The relevant mechanical properties of the material are determined by the remaining 3–4% which is a high molecular weight glycoprotein. The glycoprotein, a polyelectrolyte, is highly expanded in water, and individual molecules are crosslinked to form a gel network[4]. The presence of this

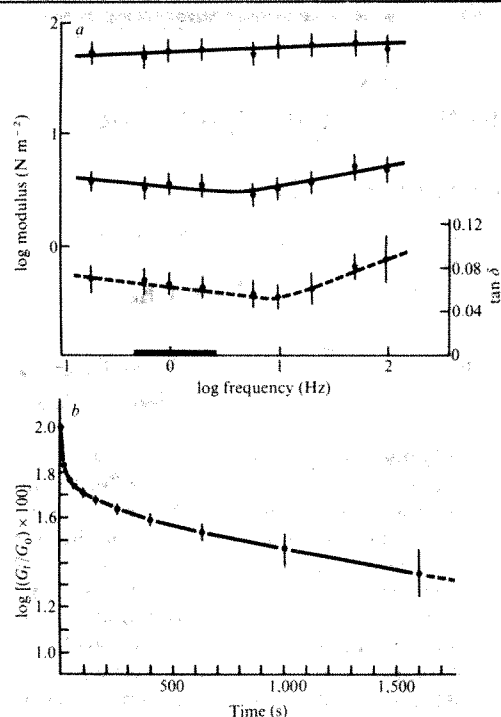
* Present address: Department of Zoology, University of Washington, Seattle, Washington 98195


Fig. 1 Network properties of pedal mucus. [Stress is force divided by area (Nm^{-2}); shear strain is shear deformation divided by sample thickness[6].] *a*, The dynamic stiffness of *A. columbianus* pedal mucus at small strains. Results shown are the average from six samples tested in air at 100% relative humidity, 22–23 °C. The bars are 95% confidence intervals. Tests are performed by applying a sinusoidal strain ($\gamma = 0.2$ to 0.5) and measuring the resulting stress. Stress amplitude/strain amplitude is G^*, the complex modulus, a measure of the material's stiffness at a given frequency[6]. The phase shift between strain and stress (δ) is a measure of the relative viscous and elastic contribution to G^*: G', the storage modulus, $=G^* \cos \delta$, and is a measure of elastic stiffness. G'', the loss modulus, $=G^* \sin \delta$, and is a measure of viscous stiffness. The ratio G''/G' is $\tan \delta$. The parallel plate dynamic apparatus (from ref. 8), was modified to test samples in shear rather than in tension. The bar on the abscissa shows the approximate range of frequencies at which the mucus is deformed under a crawling slug. *b*, The stress relaxation behaviour of *A. columbianus* pedal mucus. In the relaxation tests a sample is quickly deformed to a set strain and the force required to maintain that strain is followed with time. The curve shown is the average of 10 tests carried out in air at high relative humidities, 21–23 °C. The bars are 95% confidence intervals. Values on the ordinate are the ratio of the shear modulus at time $t(G_t)$ to the shear modulus at the start of the test (G_0), plotted as the logarithm. No small set of relaxation times adequately describes this relaxation behaviour.

crosslinked network accounts for any elasticity shown by the mucus[5,6]. The nature of the crosslinks was determined by examining the material's solubility. The glycoprotein network is not readily soluble in water, but is soluble in 1% 2-mercaptoethanol and in 8 M urea or 8 M guanidine HCl. Solubility in 1% 2-mercaptoethanol indicates the presence of disulphide bonds as network crosslinks[7], formed between the cysteine molecules which comprise 3% of the amino acids of the protein chains. Solubility in 8 M urea or 8 M guanidine HCl is evidence of the presence of a second form of network crosslink—hydrogen bonds and/or hydrophobic interactions between carbodydrate chains[7].

The mechanical properties of the mucus at small shear strains, γ, (Fig. 1 legend) were measured in a parallel plate dynamic testing apparatus (modified from Gosline[8]). This apparatus allows the elastic (G') and viscous (G'') components of the material's dynamic stiffness (G^*) to be measured as a function of the frequency of deformation. At small deformations ($\gamma < 5$) the pedal mucus shows the properties of a soft, primarily elastic solid (Fig. 1a). G' is 100 N m^{-2} (10^{-4} times the stiffness of rubber) and G'' is about 8 Nm^{-2}. Both values are virtually constant from 0.1

to 100 Hz. The stress relaxation properties of the mucus were measured at small strains ($\gamma < 5$) with a cone and plate apparatus in which the mucus is held between a small angle acrylic plastic cone and a coaxial aluminium plate. Rotation of the plate by an electric motor shears the mucus, and the consequent force is measured by monitoring (with a linearly variable differential transformer) the torsion of the bar supporting the cone. The theory of this apparatus is described by Ferry[6]. The gel stress relaxes without reaching equilibrium (Fig. 1b), indicating[6] that the network crosslinks, while stable over short times encountered during dynamic testing (milliseconds to seconds), are labile under stresses applied for long periods (minutes to hours).

These mechanical properties, although representative of the mucus at small strains, will not necessarily apply if higher strains are encountered during locomotion. The thickness of the mucus layer (measured by a method similar to that used by Lissman[9] for slugs crawling on aluminium foil) is typically 10–20 μm. The surface of the foot of *A. columbianus* moves forward about 1 mm with each wave; and the strain is thus 50–100, considerably higher than that used in the tests described above.

The properties of the pedal mucus at large strains were measured with the cone and plate apparatus. At $\gamma = 5$ to 6 the mucus network is disrupted and the material yields (Fig. 2a). With further extension the mucus shows the properties of a viscous liquid. The magnitudes of the yield stress (σ_y) and the

flow stress (σ_f) increase with increasing strain rate (Fig. 2b), while the yield strain does not vary with strain rate. If, after the mucus has yielded, the material is allowed to stand unstressed, the mucus will 'heal' that is, as the mucus stands the gel network reforms, and the material again shows the properties of an elastic solid. The mucus can be shown[4] to regain appreciable solidity in times as short as 0.1 s. This 'yield–heal' cycle can be repeated 20 to 30 times without change in either σ_y or σ_f. The precise mechanism of the healing process is not known, though it seems likely that it involves the easily reformed hydrogen and/or hydrophobic bonds of the gel network rather than the covalent disulphide bonds.

The yield–heal characteristics of this mucus are ideally suited to the locomotion of *A. columbianus*. During locomotion 12 to 17 muscular waves are present on the slug's foot; each wave being an area of forward motion, initiated at the posterior end of the animal as the tail is pulled forward. A wave is translated anteriorly until it reaches the head of the animal where it is dissipated as the head moves forward. In a small area (50–100 μm long anterio-posteriorly) at the leading edge of a wave the mucus is stressed to yielding; consequently most of the wave area moves over mucus in its liquid form. This liquid offers little resistance to movement. The waves alternate with interwaves, these being stationary relative to the ground. The mucus beneath the leading edge of the interwave quickly heals, and most of the interwave rests on mucus in its solid form. If the shear strength of the solid mucus (σ_y) is sufficient to resist the forces produced by the movement of the waves, the animal will be able to crawl forward. The mechanical properties reported here can be combined with precise measurements (from video tapes) of foot movements and areas to produce a model of the forces operating under a moving slug. The model predicts that the mucus beneath the interwaves is indeed capable of resisting wave forces, and these predictions prove accurate when compared to those forces actually measured under *A. columbianus* crawling horizontally[10]. Thus the yield–heal cycle of the pedal mucus allows it to act as a material ratchet, facilitating forward movement, but resisting backward movement. The result is effective adhesive locomotion.

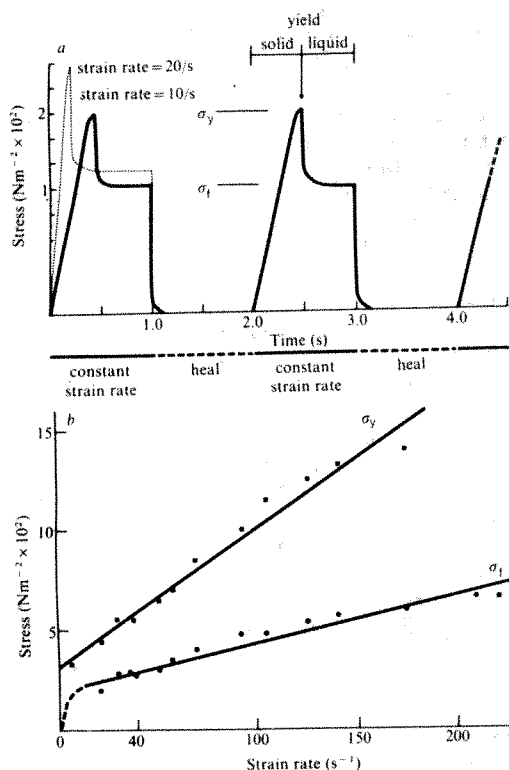

Fig. 2 Properties of pedal mucus under simulated natural conditions. *a*, Mechanical properties of *A. columbianus* pedal mucus at high strains. The abscissa is calibrated in seconds, where for alternate periods the mucus is sheared at a constant strain rate and held stationary. The mucus is thus exposed to conditions analogous to those found under a crawling slug. When first sheared, stress is proportional to strain, indicating that the mucus is an elastic solid. At a strain of 5–6 (stress = σ_y) the mucus yields. With further strain stress is proportional to strain rate, that is, the mucus behaves as a liquid. When shearing is stopped the mucus begins to heal. The healing period of 1 s represents the time the mucus is unsheared beneath an interwave during locomotion. Yield stress and flow stress both increase with increasing strain rate; yield strain is constant. *b*, A representative plot of yield stress (σ_y) and flow stress (σ_f) as a function of strain rate. The range of strain rates is approximately that found under crawling slugs. While σ_f is linearly related to strain rate at the rates measured, it is assumed to have a nonlinear behaviour (shown by the dashed line) at strain rates below those measured in these tests. [σ_y:$y = 6.9x + 313$; $r = 0.986$. σ_f:$y = 2.3x + 199$; $r = 0.971$]

Inhibitory effect of prolactin on ovulation in the *in vitro* perfused rabbit ovary

Yasuo Hamada, Sheldon Schlaff, Yoshimune Kobayashi, Rosie Santulli, Karen H. Wright & Edward E. Wallach

Department of Obstetrics and Gynecology, Pennsylvania Hospital and The University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania 19107

Prolactin is best known for its effects on the breast, promoting mammary growth and lactation. In some species, including rat, mouse, hamster, sheep and rabbit, prolactin is necessary for the maintenance of the corpus luteum[1-5]. Further, a relationship has

been recognised between hyperprolactinaemia and ovulatory failure in the human. The site of action is thought to be the hypothalamus and or adenohypophysis[6]. McNatty *et al.*[7] have postulated a direct ovarian effect of prolactin, reporting that low prolactin levels were essential for progesterone production by preovulatory human granulosa cells cultured *in vitro*. However, high levels of prolactin decreased progesterone production. The present investigation sought to determine the effect of prolactin on ovulation using the *in vitro* perfused rabbit ovary preparation. We report that its effects are inhibitory.

The technique for cannulating the rabbit ovarian artery and details of the *in vitro* perfused ovary system have been described previously[8,9]. Using this system, ovulation can be achieved following the direct addition of human chorionic gonadotropin (HCG) to the perfusion medium[9,10]. The ovaries are continually observed for 12 h to determine the state of follicular development and ovulation. Follicles are considered ruptured when an extruded cumulus oophorus is observed on the ovarian surface.

Two series of experiments were carried out. In the first, the dose of prolactin was kept constant, while the amount of HCG was varied. In the second series, a standard amount of HCG was used, while the dose of prolactin was varied. Five groups of five rabbits each were used in the first series. Both ovaries were removed from an isolated, untreated, sexually mature New Zealand white rabbit and placed in the perfusion chamber. Ovaries were perfused at a rate of 1.5 ml min^{-1}. Ovine prolactin (100 μg) was dissolved in 1 ml of saline, 1 ml of the prolactin solution was added to the perfusate of one ovary (final concentration in the perfusate 100 μg per 150 ml) and 1 ml saline was added to the contralateral ovary, which served as a control. Ten minutes later, HCG (15, 25, 50, 75 or 100 IU per 150 ml) was added to the perfusate of each pair of ovaries.

In the second series of experiments (three groups of five rabbits), varying amounts of prolactin (5, 15 or 45 μg prolactin per 150 ml) were added to the perfusate of the experimental ovary. A standard dose of HCG (50 IU per 150 ml) was added to the perfusate of both ovaries 10 min after the addition of prolactin. The contralateral ovary was perfused with HCG only and served as a control.

The total number of mature follicles observed at the onset of the experiment did not differ significantly among the groups, suggesting that the pool of follicles available for ovulation was similar in all ovaries. In the control ovaries, a relationship was demonstrated between the number of ovulations per ovary and the dose of HCG, with maximal effectiveness attained at a level of 50 IU per 150 ml (1.55×10^{-9} M). The number of ovaries which demonstrated ovulation did not differ significantly among the five control groups. Inclusion of 100 μg prolactin (2.67×10^{-8} M) significantly reduced the following parameters: the

number of ovulations per ovulating ovary in response to 25 or 50 ($P < 0.05$) units of HCG (Student's *t*-test), and the number of mature follicles proceeding to rupture in response to 15 ($P < 0.01$), 25 ($P < 0.005$), 50 ($P < 0.005$) or 100 ($P < 0.05$) units of HCG (χ^2, Yate's correction). All data are included in Table 1. In those experiments in which the dose of HCG was maintained at 50 IU and the amount of prolactin varied, the number of ovulating ovaries was not significantly reduced regardless of the dose of prolactin.

Endogenous luteinising hormone (LH), evoked by mating or by the administration of HCG, promotes follicular development and ultimate rupture within 12 h in the intact rabbit and in the *in vitro* perfused rabbit ovary. HCG was effective at various dose levels, as low as 15 IU per 150 ml, in promoting ovulation. The addition of prolactin to the perfusate reduced the occurrence of ovulation. This effect seemed to be dose related and was observed with 100 μg per 150 ml; lower doses were ineffective. Prolactin at 100μg uniformly inhibited ovulation regardless of the dose of HCG.

Prolactin exerts a dual effect on ovarian function. It is required for maintenance of the corpus luteum in certain species, and elevated levels of prolactin have been associated with attenuated corpus luteum function[11]. McNatty *et al.*[7] demonstrated that prolactin at 100 ng ml^{-1} inhibited progesterone production in cultured human granulosa cells whereas a low level of prolactin was necessary in the culture medium to promote progesterone production. The dose-dependent relationship encountered in the present experiments also suggests that at certain levels prolactin interferes with follicular rupture.

Several explanations may be proposed for the inhibitory effect of prolactin on ovulation observed in these experiments. Prolactin may act directly at the level of the ovary, independent of HCG, to inhibit final stages of follicular maturation, follicular rupture or ovum maturation. Nolin[12], using immunohistochemical techniques, has indicated the presence of prolactin in luteal cells and in dictyate oocytes of primordial and maturing ovarian follicles, in the rat, and speculates that prolactin may act to provide nutritive support for the developing oocyte. Prolactin may also influence the number of LH receptors in the follicular cells; an interaction may exist between LH and prolactin and their respective receptors at the ovarian level. In the rat, LH acts on granulosa cells of mature follicles to increase prolactin receptors[13], whereas increased prolactin leads to an increase in basal ovarian LH receptors[14]. Rolland *et al.*[15] have demonstrated an inhibitory effect of prolactin on the restoration of normal cycling levels of LH in postpartum women, suggesting that this effect of prolactin is exerted at the level of the ovary itself. Only when prolactin levels were low did ovulation and LH return to normal. Prolactin may also act as a competitive inhibi-

Table 1 The effect of prolactin (PRL) on ovulation in the *in vitro* perfused rabbit ovary

Treatment	No. of ovaries ovulating ($N = 5$)	No. of ovulations per ovulating ovary (mean ± s.e.)	No. of ovulations per no. of mature follicles

HCG 50 IU + PRL 5 μg	4	2.75 ± 0.85	$11/32$

tor of the action of HCG on the ovarian receptor.

The precise point at which prolactin interferes with ovulation is difficult to identify. Prolactin may act by interfering with final critical stages of follicular development which ultimately lead to ovulation or with mechanical events within the ovary that are required for rupture of a mature graafian follicle. In any event, these data provide additional support for the concept that prolactin acts directly on the ovary to influence the process of ovulation. This effect seems to be dose related.

Direct evidence for a two-signal mechanism of cytotoxic T-lymphocyte activation

Hung-Sia Teh & Soo-Jeet Teh

Department of Microbiology, University of British Columbia, Vancouver, British Columbia, Canada V6T 1W5

The cellular requirements for the activation of cytotoxic T lymphocytes to alloantigens are complex. In addition to cytotoxic precursors (CLPs), metabolically active stimulator cells[1], adherent accessory (A) cells[2,3] and antigen-specific helper T cells[4] are also required. However, the requirement for A cells[5,6], metabolically active stimulator cells[7,8] or helper T cells[9] can be replaced by soluble factors or co-stimulator (CoS)[10], a lymphokine obtained by stimulation of murine spleen cells with concanavalin A (Con A). We show here that in the presence of CoS, cultures containing on average one lymph node lymphocyte (LNL) and Con A can be activated to produce single cytotoxic clones. This observation strongly suggests that one of the target cells of CoS is the CLP and provides more direct evidence for a two-signal mechanism for cytotoxic T lymphocyte activation.

Culture conditions limiting for CLPs can be achieved by supplementing limiting numbers of responder cells with nu/nu spleen cells syngeneic to the responder[11]. The efficacy of CoS in rendering culture conditions limiting for CLP was therefore compared with that of nu/nu spleen cells (Table 1). It is clear that in the conditions specified in Table 1, CoS is more effective than nu/nu spleen cells in promoting a cytotoxic response to alloantigens. The frequency of CLPs in C57BL/6J(B6) (H-2[b]) mice to DBA/2(D2)(H-2[d]) alloantigens in CoS-supplemented cultures was 2,844 per 10^6 H-2[b] LNLs and 1,642 per 10^6 H-2[b] LNLs in H-2[b]-nu/nu spleen cell-supplemented cultures. H-2[b] LNLs cultured with CoS alone in similar conditions did not give

Table 1 CoS can substitute for nu/nu spleen cells in limiting dilution assays

Microcultures were set up in V-bottom microtitre trays (Cat. No. 76-024-05, Linbro) as previously described[11]. Each culture contained the indicated additions in a volume of 0.20 ml and was incubated for 5 days at 37 °C in 5% CO_2 in air. The culture medium used was RPMI-1640 supplemented with 10% fetal bovine serum (batch no. C791224, Gibco), 5×10^{-5} M 2-mercaptoethanol, 10 mM HEPES buffer and 50 μg ml^{-1} gentamycin sulphate (Sigma). B6 LNLs were taken from the brachial, auxillary and inguninal nodes. After 5 days, each culture was assayed for cytotoxic activity against 2×10^3 ^{51}Cr-labelled P815 (H-2[d]) target cells as detailed previously[14]. Briefly, 0.10 ml of supernatant was removed from each culture and 2×10^3 ^{51}Cr-labelled P815 target cells in 0.10 ml were then added to each culture with a 100-μl Eppendorf pipette, suspending the cell pellet in the process. The microtitre trays were then centrifuged at 120g for 5 min before being incubated for a further 4–6 h at 37 °C. Spontaneous release was determined by taking the mean of the ^{51}Cr release from 12 cultures that had received all other additions except B6 LNLs. The spontaneous release of ^{51}Cr-labelled P815 targets in all experiments was 10–20% of the maximum releasable counts; this was determined by freezing and thawing the target cells three times. Test cultures were scored as positive if their counts exceeded the 95% confidence limits of the spontaneous counts. The results remained unchanged if the responding cultures were taken as those that exceed the 99% confidence limits of the spontaneous counts.

Per cent specific lysis

$$= \frac{\text{Test counts} - \text{Spontaneous release}}{\text{Maximum releasable counts} - \text{Spontaneous release}} \times 100\%$$

*Fraction II co-stimulator was prepared according to the method of Shaw *et al.*[32]. A concentration of 1 unit ml^{-1} of CoS was defined as the amount that produced 37% of the maximal stimulation of DNA synthesis of murine thymocytes cultured at 5×10^5 per ml and mitogenic concentrations of Con A for 3 days[32]. Maximal DNA synthetic responses were usually obtained with about 5 units ml^{-1} CoS.

† This was calculated according to the method of Porter and Berry[33]. All the data reported here gave satisfactory fits to the zero order term of the Poisson distribution ($P < 0.05$) according to χ^2 statistics.

rise to any detectable cytotoxic response to H-2[d] (data not shown); this suggests that CoS does not exert its action by acting as a T-cell mitogen[10]. Supernatants from secondary mixed lymphocyte reactions (MLR) also contain factor(s) that renders culture conditions limiting for CLPs[12].

The above observation is consistent with a two-signal mechanism for the activation of CLPs[13,14]. According to this model, a CLP is first stimulated by antigen (signal 1). The antigen-stimulated CLP is then activated to cell proliferation and differentiation by a non-antigen-specific inductive factor (signal 2). The definitive experiment to test this hypothesis will require the isolation of a CLP and the demonstration that when it is stimulated with the specific H-2 alloantigen and CoS, it will form a cytotoxic clone specific for that H-2 alloantigen. Because the frequency of CLPs to H-2[d] alloantigens in H-2[b] mice is about 2,844 per 10^6 LNLs, only about 1 in 350 cultures containing single LNLs can form a cytotoxic clone to H-2[d] when stimulated with CoS and H-2[d] alloantigens. This approach is unfeasible, as thousands of cultures would have to be set up to obtain a statistically reliable number of responders. However, about 1 in 40 H-2[k] LNLs can be activated by Con A to form a

cytotoxic clone in nu/nu spleen cell-supplemented cultures[15]. Rather similar results were observed for CoS-supplemented cultures; the frequency of CLPs in $H-2^b$ LNLs able to give rise to a cytotoxic clone is about 31,804 per 10^6 LNLs and about 11% of these clones are specific for $H-2^d$ alloantigens (Table 2). Cytotoxic clones of all H-2 specificities were assayed for by adding phytohaemagglutinin (PHA) to the cytotoxic assay and cytotoxic clones specific for $H-2^d$ assayed for by adding α-methylmannoside to the cytotoxic assay. PHA reveals nonspecific cytotoxicity by agglutinating cytotoxic T lymphocytes to target cells[16] whereas the addition of α-methylmannoside allows the detection of specific cytotoxic lymphocytes by preventing any nonspecific, Con A-mediated interactions between cytotoxic lymphocytes and targets[17]. About 1 in 30 cultures containing single $H-2^b$ LNLs can be stimulated by Con A and CoS to form a cytotoxic clone; it is therefore feasible to test whether Con A and CoS can activate cultures containing as few as one LNL per culture. Cultures were set up such that on average each culture would contain 1, 3 or 10 $H-2^b$ LNLs, CoS and Con A. After 5 days, these cultures were assayed for cytotoxic activity against $H-2^d$ targets in the presence of PHA. The results from three experiments showed that out of 240 cultures containing an average of 1 $H-2^b$ LNL, the numbers of cultures giving rise to detectable cytotoxic clones were 7, 11 and 6, respectively (Table 3). In all three experiments, the observed numbers of responders for cultures containing 1, 3 or 10 $H-2^b$ LNLs were within those predicted by Poisson statistics; the mean CLP frequency for these three determinations is $30,876 \pm 5,369$ per 10^6 B6 LNLs. A log–log plot of lytic activity per culture against cell dose was linear and gave a slope of 1.06 (Fig. 1), further suggesting that the only limiting cell type in these cultures is the CLP[18]. These findings provide relatively direct evidence that the minimal conditions for the activation of CLPs are mitogenic concentrations of Con A and
Fig. 1 Log plot of cytotoxic activity per culture against responder cell dose, Cultures containing the indicated number of B6 LNLa were stimulated with $2.5\ \mu g\ ml^{-1}$ Con A and $7.5\ units\ ml^{-1}$ CoS in V-bottom trays for 5 days; total volume 0.10 ml. On day 5 each culture was assayed for cytotoxic activity against 2×10^3 ^{51}Cr-labelled P815 target cells in the presence of $10\ \mu g\ ml^{-1}$ PHA. The number of responding cultures for each cell dose is given in the last column of Table 3. Cytotoxic activity was calculated according to the method of Miller and Dunkley[34] and is defined as $-\ln(1-f)$, where $f =$ fraction of target cells damaged. At low f values, $f = p =$ fractional specific ^{51}Cr release. This method of expressing the data yields a number proportional to the number of effector cells present rather than the number of target cells destroyed. A value of 0.10 corresponds to 10% specific ^{51}Cr release and a value of 0.30 corresponds to 26%. The vertical bars represent the standard errors.

Table 2 Activation of CLPs by Con A and CoS

B6 LNLs	CoS (units ml^{-1})	Con A ($\mu g\ ml^{-1}$)	% Specific lysis (mean ± s.e.)	No. of responding cultures	CLPs per 10^6 LNLs
0	7.5	2.5	0.0 ± 0.4	0.12	
40	7.5	2.5	12.2 ± 5.4	7/12	31,804*
80	7.5	2.5	29.7 ± 4.8	12/12	19,670–51,424
160	7.5	2.5	41.9 ± 4.3	12/12	$\chi^2 = 2.00$
0	7.5	2.5	0.0 ± 0.3	0/12	
400	7.5	2.5	5.4 ± 1.4	8/12	3,617†
800	7.5	2.5	18.4 ± 6.7	12/12	2,185–5,989
1,600	7.5	2.5	23.6 ± 4.7	12/12	$\chi^2 = 1.31$

Culture and assay conditions were similar to those described in Table 1 legend. In the absence of exogenous CoS no cytotoxic response was detected in similar experimental conditions.
*This assay was carried out in the presence of $10\ \mu g\ ml^{-1}$ PHA.
† This assay was carried out in the presence of 25 mM α-methylmannoside.

Table 3 Activation of single CLPs by CoS and Con A

B6 LNLs	CoS	Con A	Expt 1	Expt 2	Expt 3
0	7 units ml^{-1}	2.5 $\mu g\ ml^{-1}$	0/24	0/24	0/24
1	7 units ml^{-1}	2.5 $\mu g\ ml^{-1}$	7/240	11/240	6/240
3	7 units ml^{-1}	2.5 $\mu g\ ml^{-1}$	14/120	6/124	12/120
10	7 units ml^{-1}	2.5 $\mu g\ ml^{-1}$	30/96	14/60	13/60
30	7 units ml^{-1}	2.5 $\mu g\ ml^{-1}$	ND	ND	15/24
100	7 units ml^{-1}	2.5 $\mu g\ ml^{-1}$	ND	ND	12/12
CLPs per 10^6 LNLs			37,074	27,644	27,911
95% confidence limits			28,216–48,711	19,672–38,846	19,659–39,625
χ^2			0.52	4.44	0.91

Culture conditions were similar to those described in Table 1 legend except that the total volume of each culture was 0.10 ml instead of 0.20 ml. The cytotoxic assays were carried out in the presence of $10\ \mu g\ ml$ PHA. The spontaneous release was determined by averaging the counts of 24 cultures that received CoS and Con A but no B6 LnLs. ND, Not determined.

CoS. Our data also support other studies showing that T-cell activation and clonal expansion require Con A and Con A-induced growth factors[19-21]. Further support for the two-signal model is provided by the recent observation of Lalande *et al.*[22] that a clone of specific cytotoxic T lymphocytes can be produced from a single CLP in the presence of alloantigen and CoS.

The other question pertinent to this discussion is whether CoS is the inductive signal in an MLR. CoS is not only produced following stimulation of spleen cells with Con A but is also a product of an MLR[8,23]. Stimulation of CoS production by Con A is dependent on a Lyt 1^+2^- T cell as well as A cells[5]; CoS production in an MLR also requires a Lyt 1^+2^- T cell[23] and metabolically active stimulator spleen cells[24]. Taken together, these observations suggest that CoS production is probably dependent on a Lyt 1^+2^- T cell, A cell(s) and metabolically active stimulator cells. These requirements are identical to those for optimal CL production in the MLR and further support the hypothesis that CoS is the inductive signal in an MLR. Factors bearing other names but with biological properties similar to those of CoS have been given the generic name interleukin 2 (ref. 25) and include the following: the 'nonspecific factor' of Waldmann and Munro[26], the 'nonspecific mediator' described by Harwell *et al.*[27], the 'thymocyte mitogenic factor' of Farrar *et al.*[28], certain 'T-cell replacing factors' (refs 29, 30) and the 'T-cell growth factor' of Gillis *et al.*[31].

Host-dependent evolution of three papova viruses

Eiichi Soeda*, Takeo Maruyama*, John R. Arrand† & Beverly E. Griffin†

* The National Institute of Genetics, Mishima 411, Japan
†Imperial Cancer Research Fund Laboratories, PO Box 123, Lincoln's Inn Fiels, London WC2 3PX, UK

A marked similarity has been observed in the organization of genomic information between two of the papova viruses, SV40 and polyoma virus (Py)[1], suggesting that these viruses may have diverged from a common ancestor during evolution. However, distinct differences between them and also between them and the human papova virus, BKV, are observed, for example, in their interactions with several animal cells[2], and the immunological cross-reaction between viral proteins[3,4]. Results from DNA–DNA hybridization experiments[5–8] suggest that homologies between the viral DNAs are small, although the search for homology has depended largely on the stringency of the experimental conditions. The difficulties of using hybridization (or heteroduplex) analyses for determining the extent of homology between two DNA species has been considered in detail by Yang and Wu[9]. It has also recently been pointed out that in stringent hybridization conditions, greater than 85% homology is required for the observation of double-strandedness, and that the use of less stringent conditions reveals more extensive homology between Py and SV40 than had earlier been reported[10]. Nonetheless, the above data did not seem to allow detailed discussion of the relationships between papova viruses. We therefore turned to a comparison of the nucleotide sequences of the viral genomes and found striking homologies around the DNA replication origins of these viral species[11-18]. Recently, the complete sequences of SV40[14,15] Py[19,20] and BKV DNAs[21,22] have been elucidated, providing insight into the evolutionary relationships of these viruses. We have now compared the nucleotide sequences of these viral genomes gene by gene and conclude that each of these viral species has evolved from a common ancestor and diverged with its host organism.

BKV, SV40 and Py are easily isolated from healthy human, African green monkey and mouse tissues, respectively[2,23]. They grow *in vitro* to high titres on cells from these species; therefore, we consider these to be their natural hosts. From the DNA sequence homology, we have calculated relative evolutionary distances and constructed a phylogenetic tree for the viral species. For the hosts, the evolutionary time and the relationships between species have been well documented from palaeontological studies, based on the fossil record.

According to palaeontology, the order Rodentia, which includes rats, mice and squirrels, diverged from the order Primates, to which various monkeys, the apes and man belong, about 80 Myr ago. Later in mammalian evolution, various forms of primates came into existence. In particular, the evolution of the suborder Catarrhini, a well defined group of Old World primates including the living monkeys of Asia and Africa, the

anthropoid apes and man, occurred some 35 Myr ago in the late Eocene and early Oligocene[24,25]. Therefore, applying these palaeontological facts to the evolution of the host organisms, it seems quite reasonable to suggest that the mouse separated from the African green monkey and man some 80 Myr ago and that the green monkey and man diverged from each other 35 Myr ago. Figure 1a shows the phylogenetic relationship.

For DNA sequence comparisons, data are taken from three different genes, those coding for small t antigen, large T antigen and the virus capsid proteins VP2/3. In the analysis (made by computer), the corresponding nucleotide sites of DNAs, or predicted amino acid residues of proteins, were compared and the number of identical sites or residues counted. We then calculated the ratio of the number of sites having identical nucleotides (or amino acid residues) at corresponding positions to the total number of sites (or residues) examined. We denote this ratio by P_n in the case of DNA sequence and P_a in the case of primary structure of protein. Thus, P_n is the fraction of DNA sequences which when compared have the same nucleotides, and P_a the fraction of identical amino acids. We made this calculation for parts of comparable genes for which homology was clear and for which, therefore, a meaningful comparison was possible (see Table 1). This included the entire VP2/3, small t- and large T-antigen regions of Py and SV40, a sequence of about 534 nucleotides starting from the N-terminals of VP2/3 of BKV and SV40, and others. A total of nine pairs of homologous genes from the three virus species were compared and P_n and P_a were calculated for each of them. The results are given in Table 2.

The probabilities of having identical or non-identical residues can be translated into a measure of the evolutionary distance
Fig. 1 Phylogenetic trees for hosts and for viruses. *a*, For the hosts, based on palaeontological evidence; each branch of the tree represents evolutionary divergence time. *b*, For the homologous globin amino acids; each branch represents the evolutionary distance measured by *kT*. *c*, For the viruses based on nucleotide sequence; each branch represents the evolutionary distance measured by λ*T*. *d*, For the viruses based on the amino acid sequence comparisons, each branch represents the evolutionary distance measured by *kT*. The dotted horizontal lines indicate the relative points where the branch should occur if the molecular evolutionary distances among the viruses agreed completely with the branchings of the hosts. As the dotted lines show only relative locations, one of the two lines can be placed at an arbitrary location. We have therefore adjusted the branchings between Py and SV40 (BKV) to the same height of the primates–rodent branching in *a*.

Table 1 Nucleotide usage in the measurement of evolutionary distance

	1	2	3	4
	Total	Compared	Gap	Unique
Small t antigen				
Py	639	519	3(0.6)	78
SV40	531		36(6.4)	
Py	636	513	3(0.6)	78
BKV	522		39(7.0)	
BKV	519	516	6(1.1)	6

SV40	534	534		
BKV	534			

Vertical column 1 shows the total number of nucleotides in the gene which codes for a particular protein that were examined. Column 2 shows the number of nucleotides compared. Column 3 shows the number of positions where gaps are left in sequence comparisons in order to maximize homology and (in parentheses) the percentage of sequence this represents. Column 4 shows the number of nucleotides that seem to be unique to an individual species and are therefore excluded from the comparison.

between the species compared. The method, originally developed by Zuckerkandl and Pauling[26], has been extensively used in molecular evolution studies[27,28]. The principle of the method is as follows. When we look at the evolution of genes at the molecular level, that is, at the primary sequence of proteins coded for by those genes, the rate at which amino acid residues become different is constant with time, and the probability of identity between corresponding homologous sites of two species declines exponentially with time. Because only a finite number of substitutions is possible for both amino acids and nucleotides, a correction factor must be, and has been, included in the calculations. If we denote the rate of amino acid substitution by k, that for nucleotides by λ and the divergence time by T, we arrive at $P_n = 0.25 + 0.75 \, (-8\lambda T/3)$ (ref. 28) for nucleotide identity and a similar formula for the amino acid sequence identity[27]. As P_n and P_a are experimentally determined quantities, substituting them into these formulae gives values for λT for the nucleotide comparison and kT for the amino acid comparison (see Table 2). If the divergence time is known, the

rates λ and k can be determined explicitly. It is important to realize that values of λT or kT, although they are the product of two quantities (rate and time), are of a linear nature and can be directly compared, whereas the values of P_n and P_a cannot.

Each comparison gives one value of the evolutionary distance and we have made a total of nine such comparisons for three species. Note that in corresponding parts of homologous genes, relative distances have not varied from one virus species to another (data not shown)[19]. This suggests that these regions might descend consistently from a common primordial gene. Although the evolutionary distances calculated from the data varied little from gene to gene, we have calculated a weight mean distance between each pair of species to construct a phylogeny. The result for the DNA sequences is presented in Fig. 1c and that for the amino acid sequences in Fig. 1d. For comparison, a calculation for the relevant globin sequences is shown (Fig 1b). A remarkable similarity is evident among the host phylogeny based on fossil record (Fig. 1a) and the two virus phylogenies constructed from the genome comparison at the molecular level. We take this agreement among the phylogenies as evidence for the co-evolution of the hosts and viruses. These data suggest that the three papova virus species diverged from each other together with the divergence of their host species.

It is necessary, however, to examine whether this hypothesis is consistent with other known facts. From data presented below, we have found no serious contradictions to our hypothesis.

A phylogeny based on the amino acid substitutions among homologous proteins of different species agrees well with relationships inferred from classical taxonomy and palaeontology. Proteins often used in constructing molecular evolutionary phylogenies are cytochrome c and globins[29,30]. The sequences of globins α and β are known for several species and, when the homologous chains are compared, identity indices (P_a) are found to be: man-monkey, 0.95; man-mouse, 0.85; monkey-mouse, 0.83. If these P_a values are converted into the linearized evolutionary distance ($2kT$), we get man-monkey, 0.74; man-mouse, 0.165; monkey-mouse, 0.189. From these, a phylogenetic tree of the host species can be constructed. The one based on these data is presented in Fig. 1b. With different proteins, although the distance values themselves change, the relative relationships remain approximately the same.

To determine explicitly the rates of evolution for the virus DNA and amino acid sequences (assuming the divergence times to be the same as their hosts), we calculated the rate for every case compared (Table 2). The rates for the virus proteins were found to be 4.0–7.8×10^{-9} per yr per amino acid site, which is relatively fast. The rates are known for several proteins and range from 1×10^{-9} for globins to an exceptionally slow rate of 6×10^{-12} for histone IV (ref. 31).

The virus nucleotide substitution rates were found to be about the same as that of their proteins. There are only a few reliable reports on DNA evolution rates, as DNA sequencing

Table 2 Comparison of nucleotide and amino acid sequences among the three virus species BKV, SV40 and polyoma virus (Py)

Virus lineage	Gene	Probability of identity		Linearized evolutionary distance*		No. of nucleotides examined	Ref.
		P_n DNA	P_a Protein	$2\lambda T$ DNA	$2kT$ Protein		
Py/SV40	Small t	0.453	0.306	0.98	1.25	513	13–16
	Large T	0.501	0.423	0.82	0.89	1,881	14–16, 32
	VP2/3	0.501	0.434	0.82	0.86	885	15, 33
Py/BKV	Small t	0.470	0.322	0.92	1.19	513†	
	Large T	0.425	0.407	1.09	0.93	1,380†	
	VP2/3	0.469	0.341	0.92	1.12	510†	
BKV/SV40	Small t	0.709	0.709	0.37	0.35	516	22
	Large T	0.721	0.753	0.35	0.29	1,533	21
	VP2/3	0.764	0.758	0.28	0.28	534	17

* This is divergence time (T) multiplied by rate (λ or k).

†The line-up of homologous peptides of BKV/Py is very similar to that observed in Py/SV40. Approximation to maximum homology of BKV/Py was mainly obtained by substitution of homologous peptides of BKV/SV40 into those found for Py/SV40.

techniques are very recent developments. Kimura[28] has examined nucleotide substitution rates by comparing homologous parts of the human and rabbit haemoglobin mRNA sequences. His data (based on 53 nucleotides from these genes) gives an estimate of the substitution rate for the haemoglobin genes of about 2.3×10^{-9} per yr per nucleotide site. The viral genes examined here seem to be evolving at rates of 4.5–6.5×10^{-9} per yr per site, which is somewhat faster than that estimated

for the haemoglobin genes. This is consistent with the virus protein data which show the viral proteins to be evolving faster than the globins. All the viral data can be accommodated by an hypothesis which suggests co-evolution of the virus and host species.

Avian sarcoma virus-transforming protein, pp60^{src} shows protein kinase activity specific for tyrosine

Marc S. Collett, A. F. Purchio & R. L. Erikson

Department of Pathology, University of Colorado, School of Medicine, Denver, Colorado 80262

The protein responsible for malignant transformation by avian sarcoma viruses (ASVs) has been identitifed as a phosphoprotein of molecular weight 60,000 designated pp60^{src} (refs 1–4). It has been suggested that this protein has a functional role in cellular transformation involving the phosphorylation of cellular proteins, for it was discovered that specific immunoprecipitates from ASV-transformed cells that contain pp60^{src} catalysed the transfer of phosphate from $[\gamma\text{-}^{32}\text{P}]$ATP to the heavy chain of rabbit immunoglobulin[5,6]. Additional studies involving the cell-free synthesis of the ASV src protein further demonstrated that the presence of the src polypeptide correlated with that presence of a phosphotransferase activity[7]. Our studies, involving the biochemical purification of this protein, have demonstrated that the ASV-transforming gene product, pp60^{src}, is itself a protein kinase. We have purified the pp60^{src} protein approximately 5,000-fold using either conventional ion-exchange chromatography or immunoaffinity chromatography[8,9]. The resultant partially purified preparations contain a cyclic AMP-independent protein kinase activity[8]. We report here that the soluble phosphotransferase activity of partially purified pp60^{src} results in the phosphorylation of exclusively tyrosine residues in a variety of proteins that serve as substrates.

Using partially purified pp60^{src} prepared by immunoaffinity or ion-exchange chromatography as described elsewhere[8], we have investigated the phosphorylation of a variety of proteins. Several examples are illustrated in Fig. 1. Purified pp60^{src} is able to phosphorylate the heavy chain of rabbit immunoglobulin that is immunologically directed towards pp60^{src} (TBR IgG; track 3), but not of normal rabbit IgG (track 2). Of several proteins commonly used as substrates for protein kinases, including histones, phosvitin, protamine and casein, only casein is phosphorylated by pp60^{src} (track 4). This phosphorylation of casein was largely inhibited by preincubation of the enzyme preparation with immune, but not normal IgG, demonstrating the pp60^{src}-specific nature of the

phosphotransferase activity (track 5). Using casein as the phosphate acceptor protein, we have determined the K_m for ATP to be 24 μM.

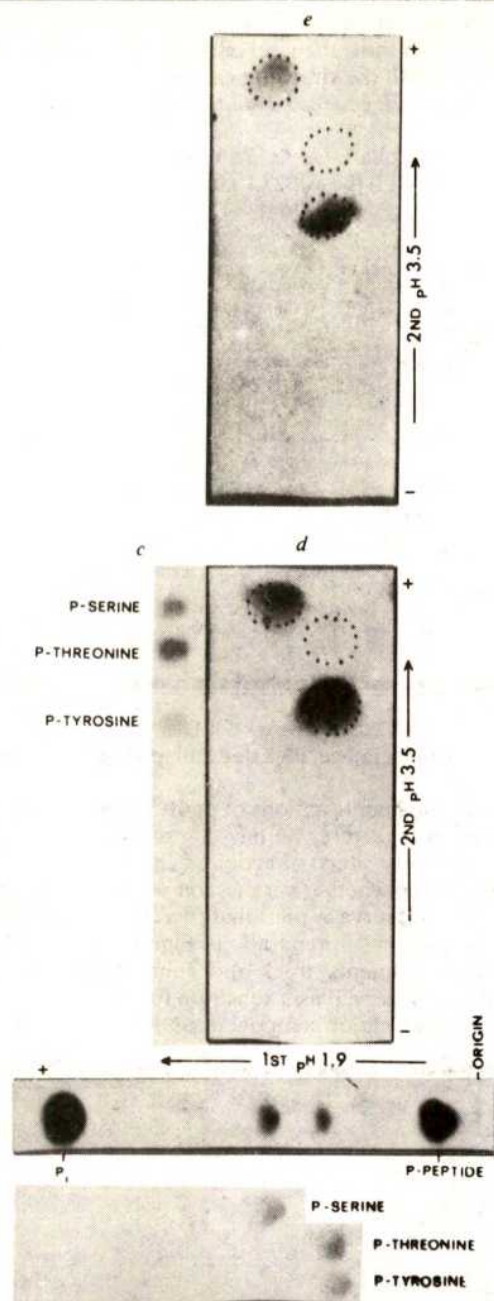
As many of the manifestations of pp60^{src} expression seem to affect cellular architecture, we have, in our initial attempts to define the molecular site(s) of action of the ASV-transforming protein, considered whether various components of the cellular cytoskeleton might serve as phosphate acceptor proteins for our partially purified pp60^{src} preparations. Figure 1 shows that actin present in microfilaments (track 6) or found in purified 10-nm filaments (track 8) served as a substrate for the pp60^{src} kinase. Desmin, the other major component of 10-nm filaments, was
Fig. 1 Phosphorylation of various proteins by partially purified pp60^{src} protein kinase. Immunoaffinity column-purified pp60^{src} was incubated in standard protein kinase reaction mixtures[8] with a variety of exogenously added proteins. After incubation at 22 °C for 15 min, reactions were terminated and samples were subjected to SDS-10% polyacrylamide gel electrophoresis followed by autoradiography[8]. Track (1), partially purified pp60^{src} kinase alone, and with (2) normal rabbit serum IgG (1 mg ml^{-1}), (3) tumour-bearing rabbit (TBR) serum IgG (1 mg ml^{-1}), (4) casein (1 mg ml^{-1}), (5) casein plus TBR IgG, (6) rabbit skeletal muscle actin (0.5 mg ml^{-1}) purified as described[18], (7) actin plus TBR IgG, (8) dog smooth muscle 10-nm filaments (0.2 mg ml^{-1}) purified as described elsewhere[19], (9) 10-nm filaments plus TBR IgG (10) chick brain microtubules (0.5 mg ml^{-1}) purified by two cycles of polymerization–depolymerization[20], (11) microtubules with TBR serum added and the immune complexes removed by addition and subsequent pelleting of protein A-containing *S. aureus* before the phosphorylation reaction. The actin and 10-nm filament preparations showed no endogenous phosphorylation when incubated alone. Endogenous kinase activity in the microtubule preparations was completely eliminated by heating at 90 °C for 1 min before the phosphorylation reaction.


Fig. 2 Phosphoamino acid analyses of pp60[src] and pp60[sarc] isolated from ^{32}P-labelled cells in culture. ^{32}P-labelled viral pp60[src] and normal chick cell pp60[sarc] were immunoprecipitated from ASV-transformed and normal chick cells, respectively, subjected to SDS-polyacrylamide gel electrophoresis, localized by autoradiography, excised and then eluted from the gel pieces. After precipitation with 20% trichloroacetic acid, the polypeptides were subjected to acid hydrolysis in 6M HCl at 100° C for 3–4 h. Samples of the hydrolysates were spotted onto Whatman 3MM paper. Electrophoresis at pH 1.9 was as described previously[10]. Electrophoresis at pH 3.5 (pyridine/acetic acid/H_2O, 1:10:189) was carried out at 4,500 V for 0.5 h. Samples of authentic phosphoserine, phosphothreonine (both from Sigma) and phosphotyrosine (initially the gift of P. Billings and M. Blumenfeld, and subsequently synthesized by the method of Plimmer[21] as modified by Mitchell and Lunan[22]) were added to all radioactive samples analysed. Panel *a* shows the results of electrophoresis at pH 1.9 of authentic phosphoamino acids (ninhydrin stained); *b*, electrophoresis at pH 1.9 of an acid hydrolysate of ^{32}P-labelled pp60[src]; *c*, electrophoresis of authentic phosphoamino acids at pH 3.5 (ninhydrin stained); *d*, two-dimensional electrophoresis (1st at pH 1.9, 2nd at pH 3.5) of an acid hydrolysate of ^{32}P-labelled pp60[src]; *e*, two-dimensional electrophoresis of an acid hydrolysate of ^{32}P-labelled pp60[sarc]. The dotted circles show the positions of ninhydrin-stained phosphoamino acid markers.

also phosphorylated (track 8), as were the two major constituents of microtubules, α- and β-tubulin (track 10). The pp60[src]-specific nature of these phosphorylations was demonstrated by prior complexing of the kinase activity with anti-pp60[src] antibody (tracks 7, 9) or by removal of pp60[src] before the phosphorylation reaction by immune complex formation and subsequent antigen–antibody removal using protein A-containing *Staphylococcus aureus* (track 11).

Note in Fig. 1 that, even in the absence of added exogenous protein, the partially purified enzyme preparation is capable of phosphorylating pp60[src] itself. This seems to be due to pp60[src] 'self-phosphorylation' (ref. 9 and unpublished data). Structurally, the pp60[src] polypeptide contains two major sites of phosphorylation[10]. One site is a serine residue located in the amino-terminal 60% of the polypeptide, which is phosphorylated by a cyclic AMP-stimulated protein kinase activity in cell-free extracts[10]. The second major site of phosphorylation on pp60[src] we had previously reported to be a phosphothreonine residue located on the carboxy-terminal 40% of the polypeptide[10]. This residue is phosphorylated by a cyclic AMP-independent protein kinase[10], and represents the site of autophosphorylation by pp60[src] (ref. 9).

Two other tumour virus-encoded transformation proteins, the polyoma virus middle T antigen and the Abelson murine leukaemia virus p120 protein, are phosphorylated at tyrosine residues by apparent autophosphorylation reactions[11,12]. We have therefore re-examined pp60[src] for the presence of phosphotyrosine and have found that our previous analyses did not separate phosphothreonine from phosphotyrosine. On re-investigation we found that the non-serine phosphorylation in the carboxy-terminal region of the pp60[src] polypeptide involves a tyrosine residue (not threonine, as previously reported[10]) in both the phosphorylated protein isolated from transformed cells and the partially purified protein autophosphorylated *in vitro*.

We had previously carried out such phosphoamino acid studies by acid hydrolysis of the polypeptide, followed by electrophoresis at pH 1.9 (ref. 10 and Fig. 2b). However, in view of the existence of phosphotyrosine in other virus-encoded polypeptides, and the fact that phosphotyrosine and phosphothreonine are not resolved by electrophoresis at pH 1.9 (Fig. 2a), we have used electrophoresis at pH 3.5 to analyse for the presence of phosphoserine, phosphothreonine and phosphotyrosine (Fig. 2c). Figure 2d shows a two-dimensional electrophoretic separation of an acid hydrolysate of *in vivo* ^{32}P-labelled pp60[src]. The first dimension at pH 1.9 allows the separation of free phosphate, phosphoserine, phosphothreonine/phosphotyrosine and phosphopeptides (Fig. 2b). The second dimension, run at pH 3.5, clearly separates phosphothreonine and phosphotyrosine. As can be seen, pp60[src] isolated from radiolabelled cells in culture contains phosphoserine and phosphotyrosine. Thus, our previous inability to resolve phosphothreonine and phosphotyrosine led to the erroneous conclusion that the COOH-terminal phosphorylated residue in pp60[src] was phosphothreonine[10]. Similar results indicating that the viral pp60[src] protein contains a phosphotyrosine residue have recently been obtained by others[13]. Furthermore, the normal cellular protein, pp60[sarc], which is both structurally and functionally closely related to the viral pp60[src] protein[14-17], also contains a carboxy-terminal phosphotyrosine residue (not phosphothreonine as previously reported[16]) in addition to an amino-terminal phosphoserine (Fig. 2e).

For further investigation of phosphorylation by pp60[src] *in vitro*, we have analysed the phosphoamino acid residues in the various phosphate acceptor proteins for this protein kinase activity. We have found that, in addition to tyrosine being the residue of self-phosphorylation by the purified pp60[src] protein kinase activity, other soluble protein substrates of this phosphotransferase activity seem to be phosphorylated exclusively at tyrosine residues (Fig. 3). Hunter and Sefton[13] have recently reported that pp60[src] present in immunoprecipitates apparently phosphorylates a tyrosine residue in IgG. Our results confirm their report (Fig. 3, track 3); but furthermore, our more con-

ventional soluble enzymatic reactions support the validity of the original src immune complex assays for the phosphotransferase activity of pp60[src](ref.5). Note, however, that only acid-stable phosphorylated residues in the various proteins are being analysed in these studies. It is possible that other acid-labile phosphorylated amino acids may be present.

It is important to realise that caution must be exercised in the interpretation of these data concerning the various substrates of the purified pp60[src] kinase. Major structural components of microfilaments, 10-nm filaments and microtubules all seem to be substrates for pp60[src] protein kinase, and all are phosphorylated at tyrosine residues only, but no information is provided concerning the physiological significance of such phosphorylations in the transformed cell.

Studies are under way to determine whether cellular proteins which serve as efficient substrates for pp60[src] phosphorylation *in vitro* are phosphorylated at the same sites in the transformed cell. Once this is established for a protein, some functional role must then be assigned to the modification observed, which can in turn be related to the transformed phenotype. In any event, due to the uncommon presence of phosphotyrosine residues in phosphoproteins, and in view of the fact that several viral proteins associated with oncogenic disease contain these phosphorylated residues, the association of such a secondary modification of proteins with cellular transformation deserves further investigation.
Fig. 3 Phosphoamino acid analyses of proteins phosphorylated by partially purified pp60[src] protein kinase. Various proteins phosphorylated as described in Fig. 1 legend were eluted from polyacrylamide gels and subjected to acid hydrolysis as described in Fig. 2 legend. Samples of the hydrolysates were then subjected to paper electrophoresis at *p*H 3.5. Authentic phosphoamino acid markers were included in all samples. Track (1), *in vivo* ^{32}P-labelled pp60[src], (2) *in vitro* autophosphorylated pp60[src], (3) TBR IgG, (4) casein, (5) desmin, (6) actin, (7) α-tubulin, (8) β-tubulin, (9) ninhydrin-stained authentic markers.

Tension generation by actomyosin thread from a non-muscle system

Fumio Matsumura, Yasuaki Yoshimoto & Noburô Kamiya

National Institute for Basic Biology, 38 Nishigonaka, Myodaijicho Okazaki, 444 Japan

A suitable motility model reconstituted from non-muscle contractile proteins should offer a powerful tool for analysing the molecular events in cell motility. Actomyosin thread has been thought to be such a model. As far as non-muscle motile systems are concerned, however, only a very limited number of experiments have been done in this direction[1,2]. No direct measurement of the tension produced by non-muscular actomyosin thread has been reported in spite of its importance for quantitative studies. We now report that a segment of actomyosin thread of *Physarum polycephalum* can generate a considerable amount of tension, which is a function of the micromolar concentration of ATP. The maximum isometric tension was as high as 10 g cm^{-2} at 10 μM ATP.

Physarum actin and myosin were purified as reported previously[3]. Actomyosin (molar ratio 1 : 1) was reconstituted by mixing actin and myosin in 20 mM imidazole buffer of *p*H 7.0, 30 mM KCl, 0.1 mM EDTA and 0.2 mM dithiothreitol (DTT). After centrifugation at 30,000*g* for 15 min, the precipitated actomyosin was dissolved in a minimum volume of 0.5 M KCl by adding 3 M KCl. Protein concentration of the actomyosin solution was 15 mg ml^{-1} as determined by the method of Lowry *et al.*[4].

To insure orderly longitudinal orientation of actomyosin, which is essential for the thread to generate tension effectively, actomyosin dissolved in the solution of high ionic strength was spun into the solution of low ionic strength as described below. The equipment for spinning consisted of three parts: (1) a syringe (Hamilton 500 μl) with a motor-driven plunger and an injection needle with a bore of 0.4 mm, (2) a shallow plastic trough filled with 20 mM imidazole buffer, *p*H 7.0, containing 30 mM KCl, 5 mM MgCl$_2$ and 0.2 mM DTT, and (3) a piece of glass tube, one end of which was fire-polished leaving a small orifice barely sufficient for the entry of the injection needle. The tube was fixed to a motor-driven sliding bench. The terminal regions of both the injection needle and the glass tube were bent and immersed in the solution in the trough facing each other with their axes in alignment with the direction of movement of the tube.

In the experiment, the actomyosin solution was loaded in the syringe and chilled in ice. The needle tip was inserted slightly

into the narrowed orifice of the glass tube. As soon as an appropriate volume of actomyosin solution had been extruded into the solution of low ionic strength in the tube, the actomyosin gelled and adhered to the tube's inner surface near the constricted orifice. The gelled actomyosin was then pulled at the rate of 2.4 mm s^{-1} by driving the glass tube away from the injection needle. At the same time, the actomyosin was extruded at the rate of 0.074 μl s^{-1} from the needle by the motor-driven shift of the plunger, with the pulling velocity four times as large as the extrusion velocity. These procedures produced flexible but strong segments of uniform actomyosin thread, 5–8 cm long and 0.2 mm in diameter. As the diameter of the gelled thread was just one-half the bore of the needle, the actomyosin gel volume did not decrease after extrusion and spinning. If the thread was formed by extrusion without pulling, it was fragile and generated only insignificant tension. Polarisation microscopic observation revealed stronger and more regular birefringence in the spun thread than in the thread formed only by spurting.

Thread segments thus obtained were mounted on a specially designed, highly sensitive horizontal-type electromagnetic tensiometer[5]. The noise level and drift were less than 0.1 mg and 0.1 mg h^{-1}, respectively. Isometric tension was measured at various ATP concentrations in the buffer solutions containing an ATP-regenerating system (20 mM imidazole buffer, pH 7.0, 30 mM KCl, 5 mM MgCl$_2$, 64 units ml^{-1} creatine phosphokinase, 4 mM phosphocreatine). Figure 1 shows the time course of tension generation in the isometric condition when 4 μM ATP was administered to the thread by perfusion. Tension increased slowly. It took 10, 6 and 4 min for the thread to reach a steady tension level after perfusion with 2, 4 and 10 μM ATP, respectively. Figure 2 shows the ATP dependence of isometric tension generation. The thread segment produced little tension below 1 μM ATP, whereas maximum tension (10 g cm^{-2}) was reached at 10 μM ATP. The half-maximum tension was observed at 2-3 μM ATP. Above 20 μM ATP, thread segments tended to break. The maximum tension of 10 g cm^{-2} is of the same order as the tension level developed by the plasmodial strand segment of *Physarum in vivo*[6]. Without the ATP-regenerating system, the sensitivity of tension generation to
Fig. 1 Isometric tension generated by *Physarum* actomyosin thread. The thread was immersed in 20 mM imidazole buffer, pH 7.0, containing 30 mM KCl and 5 mM MgCl$_2$ in an open surface perfusion chamber set on the tensiometer. A segment of thread 20–50 mm long was looped around the thin glass hook of the tensiometer and its two free ends were attached to the other hook by drying in air for 5 min. After the double thread had been straightened by moderate stretching, it was covered with the above buffer containing the ATP-regenerating system. The thread was left in the solution for 10 min to allow complete diffusion of the ATP-regenerating system into the thread. The generation of tension was initiated by perfusion of the above solution containing ATP. Net length of the double thread, 16 mm; diameter of single thread, 0.2 mm; ATP, 4 μM. When the thread was shortened by 2.5%, the tension dropped strikingly but recovered in a short time, indicating that the thread generated active tension. Temperature, 26 °C.
Fig. 2 Isometric tension level in relation to ATP concentration. Values of steady tension levels were plotted against ATP concentrations perfused. The data were obtained from six different segments of actomyosin thread. The maximum isometric tension (10 g cm^{-2}) was observed at 10 μM ATP, and the half-maximum tension at about 2–3 μM ATP. The generated tension was highly reproducible in the thread segments made from the same preparation of *Physarum* actomyosin.

ATP concentration was lower by one order. The maximum tension of 5 g cm^{-2}, or one-half that produced in the presence of an ATP-regenerating system, was reached in this case with about 200 μM ATP in the surrounding solution.

Figure 3 shows that full tension at 20 μM ATP decreased as the ATP concentration was decreased stepwise to 1 μM. When the ATP concentration increased from 1 to 10 μM, the decreased tension increased again to almost the same level as that originally developed. The state of decreased tension at 5 or 10 μM ATP did not represent rigor because the thread resumed the original tension 10–20 min after the tension was decreased suddenly by shortening by 2.5%. In short, isometric tension generation was regulated by the micromolar concentration of ATP. In the absence of the ATP-regenerating system, however, this was not the case. Tension once produced with ATP at 100 μM or a higher concentration was retained even when the ATP concentration was decreased. When the thread was shortened by a few per cent, the tension decreased markedly and was not recovered in the same ATP solution. The thread must have been in a state of rigor.

Because the preparation of synthetic actomyosin was highly
Fig. 3 Reversibility of ATP-dependent tension generation in a single thread segment. The steady tension level reached was measured when the ATP concentration was increased from 0 to 20 μM (solid line), then decreased from 20 to 1 μM (broken line), and finally increased again from 1 to 10 μM (dotted line). The number beside each symbol shows the sequence of change of the ATP concentration.

purified, the thread showed no Ca^{2+} sensitivity in tension generation at micromolar levels. Thus far we have not observed any oscillatory phenomenon, which is conspicuous in the living plasmodium of this organism, in tension production in constant ATP levels.

The actomyosin thread from *Physarum* differed from that of skeletal muscle[7] in several ways. (1) *Physarum* actomyosin thread was much more flexible, (2) the ATP concentrations sufficient to produce maximum and half-maximum tension were lower than those reported for muscle actomyosin threads, where these values were 50 and 8 μM, respectively[7], (3) tension increase in the *Physarum* actomyosin thread was slower than that in muscle actomyosin thread, where the final level of tension was reached within 2 min (ref. 7). These differences can probably be ascribed to the difference in myosin properties between *Physarum* and muscle, such as the high solubility of *Physarum* myosin at low ionic strength[8,9], a property not found in muscle myosin. Note, however, that the maximum isometric tension level reached was the same for these two different kinds of actomyosin thread with the same protein concentration[7].

A previous study on superprecipitation revealed that *Physarum* myosin formed flexible and short filaments about 0.2 μm long when it was allowed to interact with actin in the presence of ATP[3]. This suggests that such short myosin filaments may also participate in tension production by the reconstituted actomyosin thread as well as in the motility of *Physarum in vivo*.

Immunochemical identification of an actin-like protein from soybean seedlings

Thomas N. Metcalf III, Leslie J. Szabo, Karel R. Schubert & John L. Wang

Department of Biochemistry, Michigan State University, East Lansing, Michigan 48824

Microfilaments are recognised as ubiquitous cytoskeletal and contractile elements found in virtually all types of cells. Indeed, the major protein component of these fibrillar structures, actin, has been isolated from a variety of cells[1-5]. A number of laboratories have recently reported ultrastructural observations of microfilaments in plant cells such as *Avena sativa*, *Nicotiana tabacum*, *Nitella flexilis*, *Amaryllis belladonna*, *Haemanthus katherina*, *Mougeotia*, *Mimosa* and *Chara*[6-13]. Preliminary studies on the identification of the actin subunit of these structures have also been reported for *Nitella*, *Phaseolus vulgaris* and *Lycopesicon esculentum*[14-16]. More detailed studies have been made on actin isolated from the cellular slime mould, *Dictyostelium discoideum*[17,18]. We report here the isolation, from extracts of soybean (*Glycine max*) seedlings, of a protein that binds rabbit antibodies directed against calf thymus actin. The results suggest the presence of an actin-like polypeptide chain in soybean cells.

Soybean seeds were washed in 0.02% $HgCl_2$ and germinated at room temperature. All subsequent steps were carried out at 4 °C. Ten-day-old seedlings (350 g) were suspended in 700 ml 3 mM imidazole buffer (3 mM imidazole, 0.5 mM ATP, 0.1 mM $CaCl_2$, 0.75 mM β-mercaptoethanol, pH 7.5) containing 70 g of

polyvinylpyrrolidone (GAF Corporation) and 0.02 units ml^{-1} of the protease inhibitor, Trasylol (Sigma). This suspension was homogenised in a Waring blender for 4 min, filtered and centrifuged at 16,300g for 20 min. The supernatant was further clarified by centrifugation at 100,000g for 90 min.

When the supernatant fraction was chromatographed on a DEAE-cellulose column and eluted with a linear gradient of KCl (0–0.25 M), five major fractions (A—E, Fig.1) were obtained. SDS polyacrylamide gel electrophoresis (PAGE) of the material in these fractions showed that each consisted of highly heterogeneous populations of polypeptide chains (Fig. 2).

Fraction C (Fig. 1) was found to react with rabbit antibodies raised against purified calf thymus actin in Ouchterlony immunodiffusion tests[19]; no precipitin line was observed when the same fraction was tested against preimmune serum. The material in fraction C was labelled[20] with ^{125}I and immunoprecipitated[21] with rabbit anti-actin antibodies plus goat antibodies directed against rabbit immunoglobulin. Analysis of the precipitated radioactive protein components by SDS-PAGE[22] showed a single major polypeptide chain, with an electrophoretic mobility identical to that of calf thymus actin (Fig. 3). The molecular weight (MW) of this protein was estimated to be 45,000. No ^{125}I-labelled protein was observed when the preimmune serum was substituted for the rabbit anti-actin antibody.

When unlabelled calf thymus actin was added to the reaction mixture, the amount of ^{125}I-labelled soybean protein precipitated was reduced. Moreover, the decrease in precipitation of radioactivity was directly proportional to the amount of unlabelled actin added. These results strongly suggest that the precipitation of the 45,000-MW component (Fig. 3) was due to specific interactions with the anti-actin antibody.

Because the specificity of the antiserum is a key factor in the interpretation of our results, the following experiments were performed to ascertain that the antibodies were indeed specific for the actin polypeptide chain. First, calf thymus actin, isolated by a modification of the method used by Gordon *et al.*[23], showed a single band on polyacrylamide gels (Fig. 2a). Therefore, a highly purified protein was used for immunisation. Second, extracts of calf thymus tissue were labelled with ^{125}I and then precipitated using the rabbit anti-actin antiserum plus goat antibodies directed against rabbit IgG. Analysis of the immune precipitate by PAGE indicated that only a single ^{125}I-labelled polypeptide chain was precipitated. The electrophoretic mobility of this material was identical to that obtained with purified calf thymus actin (Fig. 3), the antigen used for immunisation. Moreover, parallel experiments using pre-immune serum showed no precipitation of any ^{125}I-labelled protein. Finally, the rabbit anti-actin antiserum produced a single precipitin line in
Fig. 1 Ion exchange chromatography of an extract of soybean cells on a column (4 × 25 cm) of DEAE-cellulose (Whatman DE-52) equilibrated with 10 mM imidazole, 0.5 mM ATP, 0.1 mM $CaCl_2$, 0.75 mM β-mercaptoethanol, pH 7.5. The solid line denotes the absorbance of the effluent fractions at 290 nm. At the point indicated by the arrow, a linear gradient (- - - - -) from 0 to 0.25 M KCl was initiated. The total gradient volume was 3 l. Each tube contained 10 ml of effluent.

Ouchterlony immunodiffusion tests against both the crude calf thymus extract and the purified calf thymus actin; no reaction was observed with a variety of other irrelevant proteins such as chicken muscle myosin, bovine serum albumin, fetuin and deoxyribonuclease I.

The availability of an immunochemical reagent capable of selectively binding to a single component of soybean cell extracts immediately suggested affinity chromatography as a purification step for the actin-like protein. Fraction C (Fig. 1) was chromatographed on a Sepharose column containing covalently coupled rabbit anti-actin antibodies[24]; the bound protein material was eluted with 1 M acetic acid and subjected to SDS gel electrophoresis. The gel pattern showed one predominant Coomassie blue-stained band (Fig. 2, *h*), with an electrophoretic mobility corresponding to a protein of MW 45,000. These results confirm the data from the immunoprecipitation experiments described above, obviating any interpretation problems associated with using ^{125}I-labelled proteins (such as preferential labelling of any single polypeptide chain). These results all suggest that an actin-like protein may be found in fraction C (Fig. 1) derived from extracts of soybean cells.

Actin has been isolated and characterised in a variety of animal muscle and non-muscle cells[1-5], as well as in other organisms such as *Mycoplasma pneumonia*[25], *Chlamydomonas*[26], *Physarum*[27,28], *Acanthamoeba*[23,29,30], *Saccharomyces cerevisiae*[31] and *Dictyostelium*[17,18]. In practically all cases studied to date, the various actins are remarkably similar to each other and to muscle actin, all consisting of globular subunits of approximately 45,000 MW. This identification of an actin-like protein from soybean cells with a polypeptide chain of MW 45,000 extends the list of similar proteins.

However, it remains to be demonstrated that the soybean protein shares the biological activities that have been characterised for the various actins: polymerisation into filamentous structures observable by electron microscopy, stimulation of the Mg^{2+}-ATPase activity of muscle heavy meromyosin, and stoichiometric binding of ATP. We are therefore carrying out more detailed chemical and functional analyses to compare the properties of the actin-like protein from soybean cells with the analogous proteins from other animal and plant cells.

BOOK REVIEWS

Misconceptions about Malthus

Peter Laslett

THIS book boldly advertises itself as "the best exposition of Malthus to be found anywhere". While it is a pleasure to accept this statement as true — a concise, learned, penetrating and informative treatise this most decidedly is — it has to be admitted that the competition the author has faced is rather indifferent, and with one exception it seems always to have been. For the fact is that the most important of all English-speaking social scientists; as Thomas Robert Malthus may quite justifiably be called, has been ineffectively treated by posterity.

He has had to wait for a century and a half, until last year in fact, for a full length biography, *Population Malthus* by Patricia James. An ample and painstaking account of an uneventful life lived through a very eventful period (1766–1834), the book by Mrs. James in no way rivals Professor Petersen's study. Nor has he very much to fear from an enormous list of controversial works on the most refuted amongst social theorists, works which are listed accurately and usefully at the end of his book and many of which he manages to discuss individually, mostly with insight and with fairness. His one serious rival is a writer whom some might claim had a better title than Malthus himself to be first amongst English-speaking social scientists, that is to say John Maynard Keynes. Keynes' sparkling little monograph on Malthus in his famous *Essays in Biography* cannot be said to have been eclipsed by Petersen. But Keynes, like so many of the others who have written about the mild-mannered, hare-lipped cleric and professor, used the thought of Malthus to develop a position of his own.

A great deal of the text of this book has had to be devoted to the exposure and correction of the misunderstandings of Malthusian thought, and of the fallacies which have grown up about him. Outstanding amongst these of course has been the assumption that Malthus was an advocate of birth control, a misbelief which has led to contraceptive movements being christened Malthusian. The man himself classified all interference with conception as vice. For him one of the deplorable results of the pressure of popu-

Malthus. By William Petersen. Pp.336. (Harvard University Press: Cambridge, Massachusetts/Heinemann Educational: London, 1979.) £9.50.

Thomas Malthus

Courtesy National Portrait Gallery

lation on subsistence, which he was the first to delineate in quantitative, what we should be disposed to call scientific terms, was that it impelled men in the direction of these abominable practices. The control which he advocated, indeed thought inevitable, was postponement of marriage for everyone to such a time in the life of both man and wife when they could reckon to support all the children they were likely to produce. Until that point in personal experience, a point which might never be reached by a fair proportion of persons, the expedient for avoiding procreation was abstinence.

Demographic historians now know that abstinence, within and without the married state, did in fact have a great deal to do with the successful transition to a modern low-fertility regime which took place in England some time after Malthus died. They are also becoming convinced that the sense of individual responsibility for procreation, which the nuclear family brings

with it, had been a distinguishing characteristic of north-west European familial behaviour for many centuries before the time of Malthus. In this area of the world marriage had been postponed or foregone, and individualist familial and procreative life had been led for many centuries before the time of Malthus. The catastrophe associated with his name, a catastrophe which many commentators believe awaits the population of our world, when subsistence fails to keep up with increase in numbers, was in fact less likely in the region which he inhabited in his lifetime than it has been in other parts of the globe and at other times. This in spite of the evident signs of 'overpopulation' in the England of 1798, when the first, the most trenchant and most stimulating version of his *Essay on Population* was published.

The Western European principle that every marriage means a new household and can only be undertaken when two responsible individuals are in a position to found and maintain it, may be a highly effective way of keeping a population within its means over time. It is not a principle in which the West has had a monopoly of course, but it is one which certainly causes its own hardships: for the widowed and the orphaned, and those at the margin. A further circumstance which we are beginning to recognize in Western history is that these ill consequences seem to have been compensated for socially, by means of transfers from the haves to the have-nots, flowing through ecclesiastical, charitable and above all through political institutions, only to a lesser extent through the channels of kinship.

Although this mechanism seems to have been a settled feature of the England which he knew, Malthus appears to have lacked or lost confidence in its effectiveness, and this is the outstanding interest of his position. He believed that redistribution made overpopulation inevitable, because it tended to remove procreative responsibility from individuals. Transfer incomes, he felt bound to proclaim, had to be done away with, which meant that the Poor Law, the great source of welfare for the casualties of the system, had to come to an end.

This newer view of Malthus and his significance is not one of those considered by Petersen. He is rather an indifferent guide to the demography of England in Malthusian times, and somewhat insensitive, so it seems to me, to the force of the progressive and Marxist critique of Malthusian thought. He rejects the view that the ecological crisis, which we are repeatedly told stares industrial society in the face, can properly be called Malthusian, just as he is sceptical of the views of the demographic catastrophists, as are other professional demographers.

Nevertheless it is understandable that the name of Malthus should have come to bulk so large in the learned world that at the end of this month a global meeting has been arranged to take place in Paris for the exposition and celebration of what that name has come to mean. Europeans, Western and Eastern; Africans, Asians and all the rest; those from developed and developing countries, Marxists and non-Marxists, will join together in debate about the Malthusian heritage. It can be said with confidence that he is of an intellectual standing to be worthy of such an occasion, and it is fortunate indeed that a work such as Petersen's should have appeared just in time to make that point absolutely evident.

Peter Laslett is Reader in Politics and the History of Social Structure at the University of Cambridge, UK, Fellow of Trinity College and Co-director of the Cambridge Group for the History of Population and Social Structure.

Theory and practice in thermodynamics

F.L. Swinton

Chemical Thermodynamics. By M.L. McGlashan. Pp.345. (Academic Press: London and New York, 1979.) £18, $41.50.

THERE are very many bad textbooks of thermodynamics and very few that can be considered excellent. It is a not unexpected pleasure to be able to record that Professor McGlashan's new book joins such classics as Guggenheim's *Thermodynamics* (North-Holland: Amsterdam, 1967) and Prigogine and Defay's *Chemical Thermodynamics* (Longmans, Green: London, 1954) in this latter category. The present text is designed for teaching the subject up to and beyond British honours degree level and its coverage is thus more restricted than either of these two earlier works. It is more comparable in scope to books such as those by Denbigh (*Principles of Chemical Equilibrium.* Cambridge University Press: Cambridge, UK, 1966) and by Lewis, Randall, Pitzer and Brewer (*Thermodynamics.* McGraw-Hill: New York, 1961).

One original feature is the way in which, throughout the development of the subject, theory is closely wedded to experiment. There are two early chapters entitled "Practical Thermometry" and "Practical Calorimetry", and diagrams and descriptions of various pieces of apparatus used to measure thermodynamic properties are interspersed throughout the text. Whenever a new concept or function is introduced the reader is constantly being prompted to ask the question 'How do you measure it?' The author's contention is that only by asking and answering such a question can the reader build up a true appreciation of the practicalities of the subject.

While few will dispute the need to give prominence to both theory and experiment in a textbook designed to instruct readers who may have had little or no previous experience of thermodynamics, there are bound to be some who will question the wisdom of the author's strictly axiomatic theoretical development of the subject. For example, there must be very few present-day undergraduates who will accept on trust equation (5.2.1)

$$dU^a = T^a dS^a - p^a dV^a + \sum_B \mu_B^a dn_B^a$$

that defines temperature, entropy *and* chemical potential for the first time and not question its origin. Once the axiomatic foundations are accepted, the author's subsequent derivations of all the standard thermodynamic relationships proceed with great clarity and rigour, and the university teacher as well as the undergraduate will learn much from a close perusal of the text. The treatment, in Chapters 11 and 12, of systems undergoing chemical reaction is particularly noteworthy.

One criticism that can be made of the book's subject matter is that the later, more advanced, chapters are heavily biased towards Professor McGlashan's own research interests, and whereas there are three separate chapters devoted to liquid mixtures, fluid mixtures and the principle of corresponding states, there are barely that number of pages concerned with solid–liquid equilibria. This detracts from the interest the book might otherwise have had for metallurgists and, to a lesser extent, for chemical engineers.

The book is superbly printed and produced, and one notable feature is the liberal use of footnotes. Most chapters conclude with a useful collection of numerical problems.

All university teachers will want to possess a personal copy immediately and I feel that it will not be long before McGlashan's *Chemical Thermodynamics* becomes established as a (or perhaps even the) standard teaching text in the subject.

F.L. Swinton is Professor of Chemistry at the New University of Ulster, Coleraine, Northern Ireland.

Digital image processing

P.W. Hawkes

Advances in Digital Image Processing. Edited by P. Stucki. Pp.332. (Plenum: New York and London, 1979.) $23.63.

IN 1978, IBM (Germany) organized a conference on new developments in digital image processing, the proceedings of which are published here, offset from the authors' typescripts but with a number of colour plates tipped in. The book opens with two general papers, on evolution in image science by E. Klein and H.J. Metz and on trends in digital image processing research by T.S. Huang (whose volume, *Picture Processing and Digital Filtering,* has been reissued in paperback by Springer, with a short additional chapter and many new references). This chapter by Huang brings out clearly the difficulties of digital processing and indicates some of the ways in which they may be attacked. The remainder of the book is divided into theory, applications and implementations but has in fact a strongly applied flavour throughout, even the chapters on theory showing a marked engineering bias. Thus the first of these, by H.W. Schuessler, sets out from this author's *Digitale Systeme zur Signalverarbeitung* (Springer, 1973), and is addressed to readers with a background in electrical engineering. Still in the theory section, H.G. Musmann discusses digital coding of TV signals. Lastly, H. Niemann gives a formal and very well-organized account of digital image analysis, covering preprocessing, the extraction of picture constituents or primitives, including a discussion of textures, classification (in cytology, for example) and the important step of final analysis, including syntactical, graphical and relaxation methods.

The section on applications contains six chapters, on biomedical image processing (K. Preston), X-ray images (K.H. Hoehne, M. Boehm and G.C. Nicolae), Landsat (E.E. Triendl), document reproduction (P. Stucki), computer graphics (R. Williams) and industrial automation (L. Lieberman). Preston has quite recently written a very full account of digital picture analysis in cytology (in *Digital Picture Analysis,* edited by A. Rosenfeld: Springer, 1976), and the present chapter should be regarded as a supplement to that, interesting for its discussion of Golay logic. The remaining chapters in this section show why image processing is needed in the various fields considered.

The final section is devoted to implementation : distributed processing (W. Giloi), parallel processors (M. Duff), large-scale vector/array processors (G. Paul) and a low-cost system with new fast hardware (A. Peled). For many readers,

already familiar with the methods and themes of image processing, extensively reviewed in single and multi-author volumes during the past few years, these will be the most valuable chapters of this volume. The authors explain how the particular requirements of image processing may be satisfied in recent and future generations of computer hardware.

Useful though some of the material in this book is, it can hardly be regarded as indispensable in these days of rising book prices and dwindling library budgets. It is arguable that this particular volume would have been better published as a special number of a journal than in the present form. □

P.W. Hawkes is Maître de Recherches in the Laboratoire d'Optique Electronique du CNRS, Toulouse, France.

Organic chemistry

A.R. Katritzky

Physical and Mechanistic Organic Chemistry. By R.A.Y. Jones. Pp.357. (Cambridge University Press: Cambridge, UK, 1979.) Hardback £25; paperback £8.50.

THE author has attempted a synthesis of physical organic and mechanistic organic chemistry; thus the book occupies a position between those texts emphasizing the physico-chemical aspects, such as Hammett's *Physical Organic Chemistry* (McGraw-Hill: New York, 1970) and Wiberg's text of the same name (Wiley: New York, 1964), and those dealing more directly with mechanisms such as Ingold's classic (Cornell University Press: New York/Bell: London, 1969). To attempt all this within the confines of some 350 pages is a challenge indeed, yet I believe that the author has succeeded in producing a text which will be of great value.

Part I deals with the theories and techniques of physical organic chemistry in six chapters which cover structure and mechanism, kinetics, linear free-energy relationships, acids and bases, solvent effects and molecular orbital methods.

Part II (about two-thirds of the book) covers some carefully selected mechanism types. It commences with a survey of aliphatic nucleophilic substitution, proceeds to elimination and carbon–carbon double bond addition reactions and then to aromatic electrophilic substitution. This is followed by consideration of additions to the carbonyl group, the hydrolysis of esters and aromatic nucleophilic substitution. The book ends with chapters on molecular rearrangements and pericyclic reactions.

The great strength of this book lies in its clarity which is so important in a text intended for final year undergraduates or for graduate students. The sentences are short, to the point and unambiguous. Physical organic chemistry is a subject with many unresolved controversies: here the author presents both points of view with admirable detachment.

The production of the book is good (although there was a defect in the paper on p.88 of the copy examined), and there appear to be extremely few typographical errors. The book is logically put together

and most interesting to read. It has clearly been a labour of considerable magnitude but also a labour of love.

How could the next edition be improved? I would suggest that more graphs and diagrams be included. For example, at the bottom of p.255 and the top of p.256 the points dealt with could be understood even better with a suitable plot.

In summary, I consider that the stated aims have been fully achieved: "Advanced undergraduates and graduate students using this book will be able to understand the general principles on which the study of mechanism is based and to be able to apply them to most reactions of organic chemistry". □

A.R. Katritzky is Professor at the School of Chemical Sciences, University of East Anglia, Norwich, UK.

Past and future in microtubule research

H.P. Erickson

Microtubules. Edited by K. Roberts and J. Hyams. Pp.595. (Academic: London and New York, 1979.) £34, $78.50.

THE intention of the editors was to summarize those results of microtubule research that are most exciting now and that will form the basis for the next big steps forward in the field. The authors of the 11 chapters, all of whom have made important contributions in their areas, were charged to present a critical review of the important discoveries of the past and also to stand back from their field and speculate about the important future directions. The editors have made efforts to cut overlap between chapters to a minimum so that the book would read as a coherent whole. The style and depth of coverage by the different authors varies considerably, however, and I feel that the work has to be considered as a collection of individual review articles. They are all related, more or less, but each has its individual character and some are much more successful than others.

For me the most useful chapters are in the area of cell biology. "Tubulin Pools, Synthesis and Utilization" by Fulton and

Simpson is a nice example of a critical, rather than comprehensive, review. Topics discussed range from techniques for measuring tubulin to a variety of questions of cell biology. The authors avoid vague and inconclusive lists of contradictory reports and concentrate on presenting a limited number of well-established observations and conclusions. "Microtubule-associated Cytoplasmic Transport" by Hyams and Stebbings is written in a similar style and provides wide coverage of axonal flow, chromatophore movement and some other systems of particle transport. "Cell Division" by McIntosh presents a broad review of mitosis and discusses the more conclusive studies on the location and function of microtubules. Weber and Osborn present a readable review of the application of immunofluorescence microscopy to reveal microtubule arrays in cultured cells, discussing mostly their own work.

A short article by Warner reviews evidence for the sliding of microtubules as the mechanism for motility of cilia and flagella. "Microtubules and Cell Surfaces" by Berlin, Caron and Oliver is heavily weighted towards discussion of their own work and their rather speculative models. "The Spatial Organization of Microtubules" by Tucker is even more speculative and often difficult to read, perhaps reflecting the paucity of conclusive information about how the spatial organization is determined.

In "The Structure of Microtubules" Amos presents a detailed review of results from X-ray diffraction, electron microscopy and image reconstruction. Much of the discussion is technical in nature, but for those interested in this area the article is especially timely, since the recently obtained 2 nm resolution is close to the limit of specimens and techniques currently available. "The Biochemistry of Tubulin" by Lueduña should be useful as a summary of basic information and an introduction to the literature. The biochemistry of tubulin and nucleotides, an area of increasing importance in tubulin research, is expanded in a separate chapter by Jacobs.

In vitro assembly of microtubules is covered by Scheele and Borisy in a single chapter, which is devoted largely to work from their own laboratory. Their treatment of the thermodynamics and kinetics of assembly is quite useful but their lengthy discussion of tubulin rings seems out of proportion to the importance of this subject as it is currently understood. A discussion of the assembly of purified (MAP-free) tubulin and the effect of solution conditions and ligands would have been much more valuable. This important area, which could easily have merited a full chapter, is virtually ignored in the book.

This volume should be useful to people in the microtubule field, providing them with an opportunity to review the advances of the last 15 years in areas related to but outside their immediate interests. For the person unfamiliar with microtubule research it would be difficult for any publication to provide easy access to quick answers, largely because the field is now so complex. For the student who wants to consider the subject in some depth, however, this book should be useful as a fairly comprehensive summary of results and an introduction to the literature up to 1978. □

H.P. Erickson is Associate Professor in the Department of Anatomy, Duke University, Durham, North Carolina.

Solid-state spectroscopy

Derek J. Fabian

Electron Spectroscopy of Crystals. By V.V. Nemoshkslenko and V.G. Aleshin (translated from Russian by Irina Curelaru). Pp.360. (Plenum: New York and London, 1979.) £31.19.

THE major part of this monograph comprises an extensive review of published photoelectron emission data covering a range of band structure effects in solids and solid surfaces. The book includes abundant introductory theory, of assistance to the reader both in understanding the electron transition processes involved in photoemission and Auger spectroscopies and in following the interpretations offered for many of the experimental observations.

To some extent the word 'crystals' in the title should be taken to mean 'solids', for the review covers ordered and disordered metals and alloys as well as including intermetallic and non-metallic amorphous materials. On the other hand the emphasis is largely on crystalline solids, with separate chapters devoted to sphalerite-lattice compounds, alkali and alkaline-earth halides, and transition-metal compounds.

The text commences with a helpful description of commercially available electron spectrometers, which unfortunately was already dated at the time of the original Russian version of the book in 1976. An excellent chapter on background theory — misleadingly headed "Physical principles of electron spectroscopy" — provides, for the newcomer to the field, a definitive introduction to theoretical principles of photoelectron ionization and emission, together with a descriptive outline of computative methods used for calculating energy bands in solids. The chapter on metals and alloys also contains valuable descriptive theory, including the

coherent potential method in the study of disordered systems. Further chapters deal with characterization of surfaces, including some novel aspects of quantitative analysis using angularly resolved photoemission, and with multiplet and satellite structure in photoelectron core-level spectra.

A welcome theme, throughout the review of experimental data, is the comparison of band-structure information gained from X-ray photoelectron spectra with that obtained from X-ray emission and absorption studies. Photoelectron and X-ray emission spectroscopies when combined can provide a powerful tool for probing occupied energy bands in solids. This is especially well-illustrated in the chapter dealing with core-electron and valence-band energy levels in transition-metal compounds. One topic, though, not covered adequately in the book is the determination of partial densities of electron states with various symmetries from angular distributions of emitted photoelectrons.

The monograph contains an extensive bibliography, which is particularly

comprehensive in its coverage of experimental work published in the USSR; however, its usefulness would have been enhanced by the inclusion of an author index. The book has a subject index and this too could have been improved had more detail been included. These are minor criticisms that do not detract significantly from the scientific quality of the text, which also reads lucidly and smoothly with little evidence that the original was not in English. The book can be firmly recommended both as an introductory work to students and as a valuable review to established researchers in the field. The authors set out to provide a comprehensive survey of experimental energy-band data based on photoelectron spectroscopies, drawing on their own noted research at the Ukrainian Academy of Sciences in Kiev, and to fill a gap in published monographs and reviews on electron spectroscopy applied to solid-state materials. To a welcome extent they have succeeded. □

Derek J. Fabian is Reader in Metallurgy and Materials Physics at the University of Strathclyde, Glasgow, UK.

Marking tumours

A. Munro Neville

Cancer Markers. Edited by S. Sell. Pp.541. (Humana Press: Clifton, New Jersey, 1980.) $49.50.

THE past decade has witnessed a great deal of progress in the search for biochemical markers of neoplasia. In view of their potential biological, pathological and clinical importance, it is most welcome to have a book where most of the relevant data can be found. All the chapters are informative, easily read and in the main remarkably up to date.

Among the wide range of topics discussed are aspects of alphafetoprotein (AFP), the carcinoembryonic antigen

(CEA), lymphocyte markers and pregnancy proteins, all of which are discussed from a fundamental point of view as well as in clinical terms.

Most of the other currently recognized human solid tumour-associated antigens are gathered together in one chapter thereby giving a good reference source, albeit without critical comment. The chapter on teratomas in particular is a fascinating and thought-provoking account, and the section dealing with lectins and their use as probes to dissect cell surfaces is most valuable.

This is a book of great interest to all concerned with the field of tumour markers, is timely in its publication and is highly recommended. □

A. Munro Neville is a Professor at the Ludwig Institute for Cancer Research, Royal Marsden Hospital, Sutton, UK.

OBITUARY

Feodor Lynen, 1911-1979

FEODOR LYNEN died in Munich on 6 August 1979, of complications following surgery to repair an aneurysm in his aorta. It was quite typical of the man that, while in hospital preparing for surgery, he arranged that former colleagues and friends attending the Acta Endocrinologica Congress in Munich last June should receive, personally, messages of regret that he would be unable to meet them. With his death, we have lost a great biochemist, and many, the world over, have lost a good friend.

Fitzi Lynen was a Bavarian, and proud of it. He was born in Munich in 1911; he went to school and university there and then he worked there. So great was his fame, he must have had many attractive offers from other centres of learning, but his love for Bavaria kept him in Munich. He travelled widely, however, and made innumerable lasting friendships wherever he went.

At an early stage in his career, he came under the influence of the great German chemist, Heinrich Wieland. This training and the chemical skills which he developed, and encouraged in his laboratory associates, are clearly seen in all his work. He graduated PhD in 1937, became Dozent in 1942, Professor of Biochemistry in 1953, and shortly afterwards became Director of the Max-Planck Institute for Cell Chemistry. Later, he was to become Vice-President of the Max-Planck Society, President of the Alexander von Humbolt Foundation, and President of the International Union of Biophysics. At the time of his death, he was President of the International Union of Biochemistry.

Lynen's researches aimed to elucidate the chemical details of metabolic processes, and the mechanisms of their regulation. His first brilliant observation came in 1951, when he reported in *Angewandte Chemie* that acetyl-coenzyme A is "active acetate". This was something of a surprise, since at the time it was popularly believed that "active acetate" would prove to be a phosphate. However, Lynen's keen chemical insight led him to appreciate that sulphydryl groups are acidic and that thio esters would behave like anhydrides and thus as acetylating agents.

Considering the range of topics covered by Lynen's publications, one cannot fail to be impressed by his achievements. The Pasteur effect, acetic acid degradation in yeast, the isoprene unit, biotin and the fixation of CO_2, cythohaemin, the biosynthesis of cysteine, terpenes, cholesterol and fatty acids and many others, were dealt with in papers making giant strides in the advancement of knowledge.

In recognition of this magnificient work, Lynen was honoured by universities in Europe, America and Asia. In 1964, he was awarded a Nobel Prize in Physiology and Medicine, jointly with Konrad Bloch.

Despite the honours heaped upon him Lynen remained an approachable, jovial, friendly man. Students loved him, as was abundantly evident from their contributions to his 65th birthday party, an affair which was very Bavarian and far from solemn and dignified. Working in Lynen's Laboratory was an unforgettable experience. At times, he could be a strict disciplinarian, expecting long hours of work and the meeting of deadlines, but this was always tempered by good humour and no one worked harder than Fitzi. One could not fail to be enthusiastic when he was about. Difficulties were made to be overcome, and quickly. Vast quantities of mitochondria appeared overnight, a press for breaking yeast cells was made in a day or two. It was unthinkable to leave the Laboratory before Fitzi had completed his round. Then, as the slightest excuse, or none at all, everyone, Fitzi included, would finish the day in some popular "Local", drinking beer and eating sausages. Of course, work started as usual at eight the next morning.

In 1937, Lynen married Eva Wieland, and they had five children. Frau Lynen was greatly concerned about the welfare of those who worked with her husband, and visitors to the laboratory were welcomed with charming and generous hospitality at the Lynen home in Starnberg. Much of the conversation would be about music and skiing. The number of times Fitzi had broken a leg at the latter activity was legend.

We remember Fitzi Lynen the brilliant scientist, and find it difficult to forget the jovial, limping figure, with the mischievous grin, attiring himself in his office curtains to lead the biochemists at some Faschingsparty.

J. K. Grant

L. J. Wills

LONGEVITY is not unusual in geologists, but it is rare in any branch of science to record the passing of one who continued to produce highly original and outstanding work well into his nineties, whose publications span more than seventy years, some of the later ones being among the most valuable.

Leonard Johnston Wills, Sc.D., Emeritus Professor of Birmingham University, who died on 12 December 1979, shortly before his 96th birthday, graduated with a double first at King's College, Cambridge. He was awarded the Harkness Scholarship and Walsingham Medal and a Fellowship at King's College. After four years with the Geological Survey, mapping in the Llangollen area of North Wales, he took in 1913 a Senior Lectureship at Birmingham University, and succeeded to the Chair of Geology in 1932, continuing there until his retirement in 1949.

Wills' first paper (1907) described the discovery of fossils in the generally barren Keuper rocks of the Birmingham area. This led him in later years to an interest in the fauna of other continental formations, and to extensive studies of fossil scorpions and eurypterids for which he developed ingenious original methods of dissection, revealing detailed anatomical details including the respiratory and reproductive organs.

His concern with the Trias lay also in environmental aspects — a continuing thread in his work — and in the vexed problems of stratigraphic correlation which led to one of his final papers (1976) which described the Trias of the West Midlands in terms of sedimentary rhythmic units. The volume of new information in this work justified its publication by the I.G.S., but the rhythmic units are mostly of local extent. The regional problems are now being resolved by the new science of palynology.

A further realm in which Wills made major contributions was in the Pleistocene history of the Midlands, with its story of advance and retreat of continental glaciers, recognising the evidence of extensive ice-dammed lakes of which one, which he named Lake Lapworth, covered much of the northwest Midlands. This was classic work which has served as the basis for all subsequent studies of Midlands glaciation and river development.

Wills' long term interest in the Palaeozoic rocks of Wales, in the contrasting regimes represented by the Midlands Trias blanketing concealed coalfields, in the marine later Mesozoic and in the complex deposits of the glacial period led to a series of books in which environmental aspects are a major theme. The first was his *Physiographical Evolution of Great Britain* (1929), later came *The Palaeogeography of the Midlands* (1948), *A Palaeogeographical Atlas of the British Isles* (1951), and *Concealed Coalfields* (1956).

Of these publications, the Palaeogeographical Atlas has been widely used by industry as well as by academics, being particularly valuable to the petroleum industry when North Sea exploration led to the requirement for broad regional appraisals. This made "Wills" a household name for petroleum geologists. It was a notable production, including 49 maps of Britain and the adjoining areas from the Lower Palaeozoic to the Quaternary, covering tectonics, palaeogeography, sedimentary facies and glaciation. Authorities are listed for each map — often ten or eleven individuals as well as the Geological Survey — demonstrating the thoroughness of the compilation. Many of the sources provided previously unpublished information, for example from the deep boreholes made in the course of onshore exploration for oil in the 1930s and 1940s.

Wills retired from the Chair of Geology in 1949, but his thirty years in retirement were highly productive. After the work on the anatomy of fossil arthropods and publication of his text books he continued to work on problems of the Midlands Trias and to compile data on the deep geology of England and Wales. Increasing infirmity confined him to his country home near Romsley, but he was an indefatigable correspondent and kept in touch with a range of friends who could provide a flow of new information for analysis and compilation. At the age of 89, in 1973, he completed and published a palaeo-geological map of the buried pre-Permian formations of England and Wales, a map which found an immediate place on the walls of many offices and most geological departments in the country.

It was assumed that in the face of physical frailty, with only one eye useable and a serious heart condition, this would be his last production, but two years later he followed this masterpiece with a palaeo-geological map at a deeper level — the surface of the strata with Upper Devonian and later formations removed, and this led in turn to a third map of pre-Devonian formations. Each map of this series threw new light on the deep structure and stratigraphic relations of deeply buried rocks. The last two were published together with a memoir on the data and on their interpretation in 1978, and with them his scientific work finally came to an end.

Wills had been honoured by the Geological Society by the award of the Lyell Medal (1936) and the Wollaston Medal (1954) — its highest award. In recognition of his continuing prowess he was made the only British Honorary Fellow at the age of 92. The Petroleum Exploration Society elected him a life member and helped to finance his maps, and in his last few years he received medals also from the Yorkshire Geological Society and from Birmingham University.

As a lecturer Wills was difficult to follow but inspired a generation of students with his enthusiasm and interest. In his retirement he could not have accomplished so much without the support of his old university, of a wide range of correspondents, and the devotion of his daughter who looked after him for nearly thirty years after the loss of his wife. But he attracted universal affection and cooperation, and his friends felt it a pleasure and honour to be able to help him in his continuing scientific achievement.

Peter Kent

John W. Mauchly

THE DEATH occurred on 8 January 1980 at the age of 72 of John W. Mauchly who, with Dr J. P. Eckert, conceived and carried through the project for the development of the first large-scale electronic computer. This was the ENIAC (Electronic Numerical Integrator and Computer), built at the Moore School of Electrical Engineering in Philadelphia during the latter part of the war.

Mauchly was born in Cincinnati in 1907 and grew up in Chevy Chase, Maryland. After taking his PhD at Johns Hopkins University, he went to Ursinus College as head of the physics department. During several summers he worked at the department of terrestrial magnetism of the Carnegie Institution in Washington DC, where his father was employed as a physicist. In this way, Mauchly acquired an interest in weather problems that he retained throughout his life. It was while he was working on a project for the analysis of weather records that he began to appreciate the pressing need for some automatic means of computation. He early realised the role that electronics might play and he began to do some experiments in his spare time.

In 1941 Mauchly joined the faculty of the University of Pennsylvania at the Moore School and there he met J. P. Eckert. Together, in 1942, they wrote the proposal for the ENIAC. They were able to interest the US Ordnance Department — which was facing an unprecedented wartime demand for the computation of ballistic tables — in the proposal, and as a result substantial funds were made available. The ENIAC was running by the summer of 1945 and was formally dedicated on 15 February 1946.

The ENIAC contained nearly 19,000 vacuum tubes and its construction represented an outstanding example of technological courage, both on the part of its young designers and on the part of those who gave them support. Its completion was an important landmark in the development of digital computers; however, even more significant in the long term was the formulation, by Mauchly and Eckert, in association with the ENIAC group, of the principles on which modern stored program computers are constructed.

Towards the end of 1946 Mauchly left the Moore School to found, with Eckert, the Eckert-Mauchly Corporation, intended to exploit the new ideas. All went well, although the development of a stored program computer to meet commercial standards was proving a long drawn-out process, until 1950, when they suffered a severe blow by the loss of their sponsor in an air accident. This led directly to the Eckert-Mauchly Corporation being absorbed in Remington-Rand, but happily the name UNIVAC, which they gave to their computer, has survived.

Mauchly remained with Remington-Rand, which in due course, became merged with the Sperry Corporation, until 1959, when he formed a consulting company of his own. In his later years he became associated once more, on a consulting basis, with UNIVAC.

Mauchly was a member of the National Academy of Engineering and a Fellow of the IEEE. He was one of the founders of the Association for Computing Machinery and was its President during the years 1948-50. In 1966 he received the Harry Goode Memorial Award of the American Federation of Information Processing Societies. In addition, he received numerous other honours and awards.

Mauchly was twice married. His first wife, Mary, whom he married in 1930, was drowned in a tragic bathing accident in September 1946. In February 1948 he married Kay McNulty, who had worked as a programmer on the ENIAC. She survives him, along with two sons and five daughters. Mauchly was a man of great personal charm, with a gentle approach to people and affairs. His many friends will miss him greatly.

M. V. Wilkes

The future for UK university research?

SOME time ago, the British evolved the dictum that ships should not be spoiled for a ha'porth of tar. Now they seem to think that ships can be mended with the same material and at much the same cost. Such, at least, is the response so far to the mounting evidence of the 1970s that the British university system is in danger of collapse or, perhaps worse, of lapsing into mediocrity. There is to be an examination of the mechanism for supporting academic research by a committee whose chairman is Sir Alec Merrison (Vice-Chancellor of the University of Bristol) and among whose members representatives of the research councils and the University Grants Committee are conspicuous. The immediate objective is to make recommendations about the system by means of which the two sets of bodies separately provide funds for university research. The committee hopes to have something to say by the end of the year, but that is unlikely to be more than a judicious restatement of what people in university laboratories already know — that the dual support system, regarded as a monument to the British sense of fair play in earlier decades, has now quite broken down.

British universities are not of course alone in their adversity. In most industrialised countries, governments have found it necessary to call a halt to the rapid growth of public support for university teaching and research that began, in most places, in the early 1960s. Strains have, for example, been apparent for some years in the United States, where the competition for funds by university scientists has become more fierce and where the grant-making agencies themselves have been forced to make sometimes radical reappraisals of their policies. (Is peer review as equitable as it seems, and conducive the most effective use of funds? Would block-grant support for outstanding institutions yield greater benefits and, if so, would Congress ever agree?) The British problem, however, is made much more difficult because the virtual stagnation of public budgets for the past several years has been imposed on a university system so delicately balanced between conflicting interests that it cannot respond quickly to the need for change. As the ecologists were once fond of saying, everything depends on everything else.

The dual support system is such a case. The theory is simple, even admirable. The University Grants Committee provides all the universities on its books with the facilities needed to teach students, graduate students included. The UGC grant to the universities also acknowledges the requirement of the standard contract with academics that half of a person's time should be spent on research. The research councils — the Science Research Council especially — provide extra support for individual project research and for facilities which are in principle open to all universities. (Thus the Science Research Council pays the British contribution to the European Centre for Nuclear Research at Geneva.) The research councils are also the chief source of stipends for graduate students. So, the theory has it, all academics are enabled to teach well, and to conduct research. But outstanding people can compete for extra support on the merits of their proposals.

The gulf between theory and practice has quickly widened in the past few years. That part of the UGC support for universities called the Equipment Grant (now exceeding £80 million a year), which is distributed among universities separately from recurrent costs, is often too little for university departments to meet the costs of servicing essential equipment, electron microscopes or computers for example. The general shortage of funds also requires that many academics, short of technical assistance, have to work as their own repairmen. Direct support for research is at the same time increasingly under strain. Probably it is still true that outstanding projects win support from one or other of the research councils, but there is an alarming tendency towards cheeseparing that often seems (to grant recipients) calculated to ensure that even the best projects will not quite succeed. Less than outstanding but still good projects are now at risk, as are the people employed for years on soft money (from whatever source), who must be now almost as much at risk of unemployment in mid-career as are professional footballers.

All this is quickly changing the pattern and helping further to erode the spirit of much university research. The number of university departments which lack externally funded research projects is growing, further increasing the pressure on UGC funds. The supposition that students will be taught in places where research is active is too often false for comfort. The most serious threat to the future of British university research is that young men and women with outstanding projects in their minds can no longer look confidently for niches within even sympathetic university departments where a research team can grow up. The demographic log-jam among tenured university teachers, more than half of whom are still younger than forty, is largely responsible. The shadow cast by these developments on the future is long and getting darker.

Unhappily for the Merrison committee, these are problems which can be more easily described than solved. The UGC's support of university research rests on the assumption that all academics are equally free to win reputations for themselves in research. By extension, all universities are supposed equal and are thus confirmed in their proper jealousy of their independence. Support from the research councils is, on the other hand, openly and properly discriminatory; the best projects, wherever they come from, attract support. An application from the University of the Sticks has, in theory, as good a chance as one from Oxbridge. Practice is, however, somewhat different. Willy-nilly, successful researchers find their way to places where research is already strong and, once there, attract further support for their departments' research. The lists show that Oxbridge, London and the strong civic universities predominate in the hunt for funds. To ask that such concentrations should not occur is to ask that human nature should be different. The difficulty, for Merrison, is that there can be no reform of the dual-support system that avoids offending against one or other of the principles that all universities are equal and that all academics are free to work where they like (and can find a job).

The temptation, of course, will be to tinker with the system within the limits of the fixed budgets now in prospect. Transferring some of the UGC equipment grant to the research councils, so that each project grant could be accompanied by the full cost of its overheads, would help to ensure that projects were carried out in circumstances where they might succeed, but would be resented (and resisted) by most universities and their teachers. Transferring funds in the opposite direction would be equally offensive. (Constitutionalists will quickly point out that either change would require an Act of Parliament — for which there is no time.) No doubt the committee will also canvass the fashionable notion that industry should directly support more

university research — a dubious precept unlikely to be followed eagerly in the coming recession. Yet something must be done to allow such funds as there are for university research to be concentrated where they can be spent most effectively. The time, in other words, appears to have arrived when the assumption that all universities are equal will have to be openly abandoned. Some will have to draw back from in-house research.

This is where the ructions will begin. The chance is small that a committee with such narrow objectives will discover an acceptable device for working such an important change in the character of the British university system. The ideal would be that there should be incentives for helping the universities less strong in research to work out some other role for themselves, perhaps as specialised institutions or even as liberal arts colleges. The

uniformity of the British university system has been for decades its most obvious weakness. But such a change could be brought about only by a more radical reform of higher education as a whole. Before it knows where it is, the Merrison committee will find itself agonising about the selection of graduate students (now somewhat capricious), transfer of undergraduates between one university and another (still unreasonably difficult), the length of undergraduate courses (most probably too short) and the education of secondary school students (ridiculously narrow). Its problem is both the tip of an iceberg and a can of worms. It will be solved without permanent damage only if the universities themselves seize the initiative and work out a solution for themselves. Their jealously of their autonomy has been matched in recent years only by their complacency.

Inflation, interest rates and innovation

The United Kingdom in its present condition is likely to be most other nations' illustration of how not to conduct affairs. How can it be, the question will be phrased, that within a year of the election of a government dedicated to deflationary policies, the inflation rate has almost doubled (to 21.8 per cent per annum) and is certain to go still higher? Does it follow that Mrs Margaret Thatcher has misled one of the world's oldest democracies, and should promptly be replaced as Prime Minister? Or that Professor Milton Friedman has misled Mrs Thatcher, and should be stripped of his Nobel Prize? Or is it possible — this is what people elsewhere may ask — that there is some diabolic logic in the British predicament that will in due course make its influence felt elsewhere? There, but for the grace of God, so to speak, go all of us? Or is there another box in the response-frame of this implicit multiple-choice question, something labelled "Other — please specify"?

The intelligent response, of course, is none of the first. Mrs Thatcher is much like other British Prime Ministers — quick, masterful (not synonymous with "masterly") yet unwilling to give hostages to fortune by saying publicly (or even privately) what she hopes for. The innocent Professor Friedman has done nothing worse than to point to an almost arithmetical identity — that (*ceteris paribus*) governments worried about inflation have the remedy in their own hands, by their control of the supply of money, pound notes, dollar bills or what have you. If Professor Friedman were to be robbed of his Nobel Prize simply because, ten years ago, he failed to foresee the subtlety of the ways in which people would counter the stratagems of the deflationary governments they had elected by discovering new ways of raising money or, what is the same thing, buying goods, then it would be proper that other Nobel prizewinners such as Watson and Crick should be on the same plane to the medal-returning ceremony in Stockholm for having failed to guess that reverse transcriptase would be discovered. None of them will make that journey, and rightly.

The question whether we are all destined for the same fate is more tricky. Ten years ago, the Italian economy was widely regarded as a joke in poor taste. The economic miracle of the late 1950s seemed to have vanished as mysteriously as it had arrived. Inflation bobbed around at about 20 per cent a year, a then unprecedented rate for serious industrialised countries. Governments came and went with predictable irregularity. Italy has however managed to survive, largely by means of two separate devices. First, there has been a steady erosion of the strength of social institutions, both modern and ancient. The power of the central government has at the same time steadily declined, sometimes in favour of stronger regional government, sometimes urban terrorism and sometimes both. These are but the predictable consequences of inflation and do not amount to a recipe for survival. Italy has survived in spite of inflation because Italian industry has been able somehow to keep ahead, producing a range of highly saleable commodities which have sold well abroad and

at the same time building on the reputations of Italian engineering contractors for the efficient conduct of major construction projects anywhere in the world. In short, Italy has survived more than a decade of high inflation partly by paying a heavy price and partly by the ingenious exploitation of technology.

In principle the same expedient could be followed in the United Kingdom and, for that matter, by the other potentially sick men of the OECD area, the United States and possibly even Japan. Yet circumstances are now more difficult than when Italy learned how to live with inflation. The price of oil has increased ten times. The result is not merely that prices have increased and that the financial markets are flooded with unused credit, but that the populations of the countries where inflation is highest have not accustomed themselves to the notion that the increased price of oil entails a transfer of wealth to the oil suppliers. Mrs Thatcher was right to insist, last week, that British inflation will not abate until British voters acknowledge that they are individually and collectively impoverished by the increased price of oil.

Unfortunately, in the absence of such realism, even the Italian solution is less accessible. When inflation is high and unlikely quickly to abate, interest rates are bound also to rise. This is what has happened dramatically in the United Kingdom and the United States in the past twelve months. For why should people lend their money either to governments or to those wishing to start new enterprises if they have no expectation that the real value of their money will be returned to them? In principle, of course, the arithmetical rate of interest should not be an absolute brake on innovation. People confident that some new process or product will quickly dominate its rivals can simply allow for the high rate of interest in the prices which they eventually fix for what they have to sell. Reality, alas, is not quite like that. High interest rates mean proportionately greater costs for research, development and the building of new plant. In other words, the real risks of innovation are increased. The dice are loaded against those who might help to solve their countries' problems by technical innovation.

For the United Kingdom and, perhaps later, for the United States, the consequences could be calamitous. (Japan is a different case, whose problems stem not from a lack of productivity or innovation but from the financial problems of entire dependence on imported oil.) That there is a connexion between the soundness of an economy — and in particular its freedom from inflation — and the pace of technical innovation is well attested not merely by what economists say but by the economic statistics of the past ten years. Even in the United States, the rate of growth of industrial productivity has lagged well behind that of the well-founded European states. In the United Kingdom, notoriously, the pace of technical innovation has been a snail's pace. To know that these circumstances can be remedied only if there is a profound change in ordinary people's expectations of prosperity is forbidding. Too many people have a vested interest in not saying what the truth is.

Congress may threaten NIH autonomy

Washington

FEARS for the political independence of the National Institutes of Health have once again come to the surface. The cause of the trouble is a Bill now working its way through the House of Representatives that would require that the several institutes of the NIH are funded individually by Congress.

The scientific community is alarmed that the proposed arrangements would enable Congress — or individual congressmen — to attach unworkable provisions to financial legislation. Meanwhile, the administrators of the NIH have drawn the wrath of their political bosses at the Department of Health and Human Services (previously Health, Education and Welfare) by their attempts to head off the legislation in its earlier stages.

At one stage, it is widely reported, the Director of the NIH, Dr Donald Fredrickson, was told by the Secretary of DHHS, Mrs Pat Harris, to "shut up or get out". Dr Fredrickson has stayed put.

Relations between the NIH and its sponsoring department have never been easy. On this occasion, however, the House Bill may seem a lesser evil than a similar piece of legislation introduced in the Senate last year by Senator Edward Kennedy, chairman of the Senate Health and Science Subcommittee.

Kennedy's Bill would make all the institutes of the NIH separately accountable to Congress, but would also have imposed several other unpalatable conditions on the planning of medical research. One of these persists in the version of the Kennedy Bill soon to be considered by the Senate — the proposal that NIH strategy should be determined by a sixteen-member council appointed by the President.

Waxman proposes . . .
The Administration is staunchly opposed to this condition, but appears ready to accept that separate accountability will in future be required of the institutes. This position appears to have been reached only after an acrimonious dispute within the DHHS, where Mrs Harris was at first strongly opposed to some aspects of the House Bill.

The chief consequences of the Bill as it stands will be budgetary. (Two of the eleven institutes of the NIH, the National Cancer Institute and the National Heart, Lung and Blood Institute, are already dealt with separately in Congress.)

Budget strategy will be approved on a three-year basis, with a provision that

. . . Harris disposes

spending may be continued for a fourth year if Congress fails to act. Representative Henry Waxman, chairman of the Health Subcommittee, says however that there is no intention of using the new legislation as a way of cutting individual institute budgets, which will in any case be protected by separate appropriations legislation.

In spite of Mrs Harris's wrath, the NIH have won some concessions from the House of Representatives. A limit on the amount of research grant that could be approved by an individual institute council has been increased from $50,000 to $500,000. Moreover, there is a new provision for a fund of $100 million to be spent on areas considered by the Director of NIH to be especially deserving of support.

NIH officials are still unhappy, however, with the increased role of externally appointed advisory committees in the planning of research strategy, while the extent to which the Secretary of DHHS may delegate responsibilities to the Director is, it appears, to be on the Secretary's say so.

Both the Senate and House bills are likely soon to pass in their respective chambers. In the conference that follows, it should become clear in what corner Mrs Secretary Harris is fighting.

David Dickson

Marine Pollution

Clean the Med

ELEVEN Mediterranean nations signed a treaty in Athens last Saturday (17 May) which commits them to clean up their rivers and sewage discharges, to make the Mediterranean a fit place to swim and fish in again. At present 90 per cent of the sewage from the 120 largest Mediterranean cities is poured into the sea untreated; and Italy, France and Spain sweep out their industrial pollutants through the rivers Po, Rhône and Ebro. Effective control of these land-based sources — the objective of the treaty — will cost some £6 billion, it is estimated. But 100 million tourists a year and a £300 million fishing industry will benefit.

The treaty is the sweetest fruit so far of the United Nations Environment Programme's Regional Seas Programme, which is run by Yugoslav marine scientist Dr Stjepan Keckes. He takes an optimistic view. "The British began talking about cleaning up the Thames 25 years ago. Today, salmon have returned to the Thames. I believe we can make the Mediterranean a much cleaner and safer place by the end of this decade."

The foundation of the treaty is both scientific and political: a network of laboratories around the Mediterranean coasts, many of whose staff have been trained and equipped through the Regional Seas Programme. Keckes has insisted on establishing uniform measurement procedures, and has used national laboratories (rather than a single, international expert team) to ensure the respect of national governments for their data. Keckes has also aimed the programme largely towards the definition of 'water quality objectives' rather than uniform emission standards; this has the advantage that, say, the relatively undeveloped North African coast can initially accept higher-polluting factories simply because there are fewer of them — so development is not penalised. The main burden will in fact fall on Italy, France and Spain.

The treaty will have to be ratified by six nations before it comes into force. Ratification would follow the passing of the necessary national legislation.

Two classes of pollutant are defined in the treaty: 'black list' and 'grey list' substances. Black list substances will be limited to very low emissions, because of their toxicity, persistence, or accumulation

in the food chain. These include mercury, cadmium, used lubricating oils, certain carcinogens and mutagens, and radioactive materials. Grey list substances will be admitted to the Mediterranean through strict licensing agreements which will take into account the ability of the local environment to absorb them. The grey list includes zinc, copper, lead, titanium, crude oils and hydrocarbons, pathogenic micro-organisms, and non-biodegradable detergents.

Atmospheric pollution of the sea is also covered by the treaty. Measurements on the Baltic have indicated that the air, replete with exhaust fumes, may be the principal source of organic lead in surface waters far from the coasts — but the air-sea interchange is very difficult to measure. The treaty has reinstated a deep-sea, air-borne pollutants monitoring programme which had been axed, on French insistence, a year ago. "The countries recognised it was a mistake" said Keckes.

The next step, says Keckes, is to shift the £400,000 a year research programme, from one largely for training and equipping laboratories, to one of specific common research and data handling — which will be a five- or ten-year programme.

Precise environmental quality objectives, emerging from the research programmes will be defined in time for ratification. A meeting in October is expected to set the first: for bathing and shellfish growing waters (largely a matter of micro-organism levels), and for mercury in shellfish.

Research posts

Jobs for the Jugende?

WEST German post-doctoral and just pre-doctoral scientists, searching like others the world over for scarce research positions, will shortly find another 175 posts a year open to them — if the federal and regional governments approve.

The Arbeitsgemeinschaft der Gross-forschungseinrichtunungen (AGF), an association of the 12 major research centres outside the universities, has asked the governments to back a proposal to create 700 new posts over 4 years, each lasting three to five years, at a total cost of about DM90 million (£22 million). This represents little more than an annual 1% addition to the current AGF budget.

Professor Herwig Schopper, president of the AGF, said this week that the proposal was designed to cope with a national population bulge — which is beginning to swell doctoral numbers at a time when most post-doctoral posts are already filled. "We don't want to lose this

talent just because of a freak of demography" he said. The programme fitted well with another — under discussion in the Ministry of Universities — to create more junior university positions over the same period.

In making the proposal, the AGF (whose members include, for example, the high-energy physics laboratory DESY, and the German cancer research centre at Heidelberg, the DKFZ) has taken account of the age profiles of its member laboratories. An official said this week that fewer than one scientist in a hundred currently retires each year from AGF staffs, releasing fewer than 40 posts. Another 30 are freed by scientists moving to industry, but the total of 70 vacancies is far too few to retain a stable age profile in the laboratories.

However, said the official, retirement rates will begin to rise rapidly in five years. By 1992 retirements are expected to reach 7% a year, the equivalent of 280 posts. "So we just have a valley to bridge."

The proposed appointments would be made through the usual recruitment procedures of AGF members, but specified subjects will be preferred. Thus energy research would receive 175 posts; nuclear and subnuclear physics 140 posts; life sciences 140 (with appointments principally to the DKFZ, to the Gesellschaft für Biotechnologische Forschung, and the Gesellschaft für Strahlen und Umweltforschung); information technology 105; materials science 70; aerospace 35; and technology assessment 35.

The Federal science minister, Herr Volker Hauff, has approved the scheme, but it must now go to the cabinet for a decision. And as the regional (Länder) governments support AGF laboratories to 10% of their budgets, the AGF must seek their approval also. Schopper is confident of success, but he does not expect a decision before the federal elections later this year.

Robert Walgate

Innovation

Biotechnology boom at NRDC

BRITISH biotechnology may benefit from the impending change of managing directors at the National Research Development Corporation. Dr James Cain will succeed Dr William Makinson on 1 June, and is already talking of tripling the corporation's spending on biotechnology in the coming three years.

Dr Cain, a 57-year-old biochemist, is at present head of the NRDC's biosciences group, which contributes four-fifths of the corporation's £18 million licence income.

The NRDC's major earners are the cephalosporin antibiotics — developed by Professor E P Abraham of the University of Oxford — which, said Cain last week, have already earned NRDC at least £80 million through licensing agreements set up by the biosciences group since 1959. Pyrethroid insecticides are "already into millions".

Biological projects, based on patents acquired from university and government laboratories, have thus become the NRDC's bread and butter. They also appear to be good business: the cost of developing an innovation from a successful patent to the point at which it can be licensed tends to be less for biological than for hardware projects.

Investment in hardware projects still dominates the NRDC's investment. At the last count, there were 229 active projects in fields such as instrumentation and engineering, compared with only 18 in the biological sciences. The corporation's total investment in biological projects amounts to £1.5 million, a mere tenth of the NRDC's total investment. Of this £600,000 has been committed to genetic engineering. Cain hopes the £1.5 million will be doubled or tripled in the next three years.

Cain says that the corporation has been talking to industry for some time about biotechnical projects, and one involving crop plant development "is being actively followed up", with a decision possible within six months. On the academic side, "people are coming to us with projects once a month", a vast increase on say five years ago. "We've been getting experience of genetic engineering and want to increase our exposure" he said.

Most of the NRDC's projects involve collaboration with industry, but the most natural partner for many joint ventures, the pharmaceutical industry, is so used to carrying out high-risk projects on its own that experience has been disappointing. So the corporation is looking to the food industry and elsewhere in biology-based industry where indigenous research tends to be short-term.

Cain acknowledges that NRDC spending will continue to be higher in the physical sciences because such projects tend to call for the building of expensive large-scale prototypes. But the time may come when NRDC will have to build biotechnical pilot plants, which will call for larger resources. "It's quite easy to imagine a £1 million project with industry", he says, "which aimed to go commercial in three or four years."

The new interest in biotechnology does not however mean that the NRDC's traditional interests will vanish. In particular, the corporation will continue to be heavily involved in computing machinery and in computer software. But for the time being, it seems to have an edge in biological engineering.

Robert Walgate

Ariane

Getting bigger and better

THIS is yet another milestone-week for *Ariane*, the satellite launching system developed by European governments under the aegis of the European Space Agency (ESA). Tomorrow, 23 May, the second test-flight of the *Ariane* system will be carried out from the rocket base in French Guiana. Today, 22 May, the Council of the ESA is meeting to decide how the cost of the next three years' development, estimated at 175 million units of account (about £115 million) should be shared among member states.

The plan is to improve *Ariane* to carry payloads of 2,000-2,300 kg, compared with the 1,750 kg capacity of the current launcher. The new systems will be capable of placing two 1,000 kg satellites into geostationary transfer orbit and so will fulfil most of the requirements of launching heavy telecommunications satellites.

The development is planned in two phases and *Ariane* II and III should be complete by 1983. *Ariane* II will be developed first to carry payloads of up to 1,950 kg by increasing the thrust of the first and second stage engines and the propellant mass of the third stage. *Ariane* III, with a payload of 2,300 kg, will have two boosters fitted to the first stage. The volume available for carrying satellites will be increased in *Ariane* III to allow two satellites to be launched together, reducing costs.

The stimulus for the *Ariane* programme has come from the Centre National d'Etudes Spatiales in France (France has funded 55% of the 790 million accounting units of the first phase of Ariane development over the past seven years). CNES has done much of the groundwork for *Ariane* II and III and is already planning later versions. According to M Bouillard, head of advanced projects at CNES, *Ariane* IV, which would be *Ariane* II with four extra boosters and a 35% increase in first stage development and would accommodate payloads of up to 3,500 kg, could be developed by 1985. Plans for *Ariane* V, however, are more ambitious. It would be capable of putting into orbit a manned vehicle which would return to earth under its own steam. CNES is also looking at the feasibility of recovering and re-using some components of Ariane V. It hopes to develop *Ariane* V by 1990.

In the meantime, the development of *Ariane* I is coming to an end. Earlier this year ESA handed over routine production to a consortium of European industry, Arianespace. After the four test launches (the last is scheduled for early 1981) and two subsequent launches, ESA will be free
Ariane II, second stage in the development of the ESA's satellite launcher, to be launched from French Guiana tomorrow.

of financial responsibility for further production, provided that Arianespace is financially viable. ESA member states are currently signing an undertaking to help bail Arianespace out should it ever get into trouble.

ESA will, however, retain responsibility for maintenance of the *Ariane* launch pad at Kourou, French Guiana. Member states will also decide at this week's council meeting whether to fund the building of a second pad at the site. The existing pad can handle only four launches a year. When the larger versions at the rocket come into operation, ESA estimates that up to six launches will be needed each year.

Even if, as expected, the plan for *Ariane* III is approved this week, the budget will be considerably less over the next three years than it was at the height of the development of *Ariane* I. It is unlikely, however, that much of the money released will be channelled into ESA's other programmes, in particular the science programme, which desperately needs more funds. Any increase in the science budget, which is mandatory for all member states, would have to be approved by them all. Those who do not contribute to *Ariane* are unlikely to agree to spend more.

ESA's immediate concern, though, must be the success of the second Ariane test-flight, scheduled for 23 May. The two small German satellites, "Firewheel" and "Oscar 9", carried free of charge, are also dependent on the success of the mission. "Firewheel" is a small satellite built by the Max Planck Gesellschaft to release barium and lithium clouds into the magnetosphere and monitor their movement through it. "Oscar 9" is a satellite for radio hams. If the flight goes as well as the first test, ESA and the German satellite operators should have few worries. Member governments may also pay up more cheerfully.

Judy Redfearn

Grant audits

No easy riders

Washington

THE dust is refusing to settle around conflicts between research universities and government accountants over the auditing of federally-supported research grants. It is more than a year since the Office of Management and Budget (OMB) issued the final version of its revised accounting rules, a document known as Circular A-21, hoping for a temporary pause in the skirmishing around grant accountability.

But complaints continue to mount, particularly over the requirement for detailed records of how scientists and technicians spend their time. The government's obvious interest is that funds allocated to a project should not be spent on anything else.

The suggestion is now gathering momentum that tensions may be resolved only by radical changes in the basis of research grants. One possibility is a shift from the "cost-reimbursement" basis to a fixed-price, grant-in-aid system, under which, once a grant has been awarded, research workers and their universities would decide how it should be spent.

Ample evidence of continuing frustration was voiced in Washington last week at a meeting of the advisory committee to the Director of the National Institutes of Health. It was plain that financial stringency has also exacerbated tensions between scientists and their universities.

The issue is the level of overhead costs universities should be entitled to add to research-grant proposals. Overhead percentages have increased rapidly in the past decade. The proportion of NIH grants spent on indirect costs rose from 28.5 per cent in 1970 to 41 per cent in 1979, according to a survey carried out by the National Eye Institute. On the grounds that when overall budgets are static, rising overheads mean less money for research proper, the council of the Eye Institute recommended last October that the NIH should reduce all indirect-cost allowances by a third. And the University of California's faculty Senate has rejected proposals from the University President for an increase in overhead percentages.

University administrators firmly resist such reductions, insisting that indirect costs have increased dramatically, largely, they claim, because of federal regulations, for example covering affirmative action or occupational safety. They claim that most universities are able to collect only 80 per cent or less of the costs incurred in undertaking federal research commitments. At Washington University, according to Chancellor Dr. William Danforth, the total costs of carrying out federal research and training in 1978-79 was $49.6 million, but only $40.4 million was recovered from the government.
NIH estimate of the sources of income of a typical pre-clinical research laboratory in the United States (percentages of total).

More immediately troublesome for research workers is the need to give precise estimates of how much time they spend on projects.

Circular A-21 relaxed the time-and-effort demand by agreeing that faculty members need only complete such a record at the end of every term rather than every month (reports on technicians are still required monthly), and offering the alternative of "workload monitoring" where time allocation is agreed before a project is begun.

But research workers still find the system oppressive. Many claim it is unreasonable, for example, for a research scientist in a medical school to decide how time has been distributed between functions that may have been carried out simultaneously. "It is impossible to allocate one's time between research, training and patient care, and it is a sham to try to impose it," Dr David Kipnis, chairman of Washington University's School of Medicine, told last week's meeting.

Others argue about the difficulty of shifting from the rigours of scientific quantification to the "creative fictions" of the accountant. "We put a high degree of rigour on the numbers that we generate. So when we get a form asking us to put down numbers, we tend to think that they are the same type of numbers, ignoring the fact that they may not correspond to our notion of reality," said committee member Dr Howard Temin, professor of oncology at the University of Wisconsin.

Government auditors are unbowed. They insist that the revised A-21 requirements have considerably reduced the reporting load. They also point out that current auditing requirements follow directly from the way Congress has chosen to support biomedical research.

This has prompted increasing suggestions that alternative ways of supporting research should be explored. In a report on funding mechanisms soon to be published, for example, the National Commission on

Research (NCR) suggests that experiments be made with locally-managed grants-in-aid, shifting the emphasis from detailed financial accountability to scientific accountability.

Under such a system, a grant proposal would still be closely scrutinised by the funding agency using the full peer review process. But once the money had been allocated, the investigators' prime responsibility to the agency would be to report on the technical aspects of the research. Administrative details would become the responsibility of the investigator and his or her university, with the funding system becoming the main incentive for the wise management of resources.

NIH is keen to encourage experiments along these lines for certain types of grants, according to director Dr Donald Fredrickson, while OMB officials say that, in principle, such a basis would be acceptable and simpler to administer.

In a different context, the National Science Board, the governing body of the National Science Foundation, has given some thought to the merits of block-grants to universities, so far without conclusion.

Not all universities relish the prospect of having to decide how a research worker is entitled to spend a federal grant. In addition to the increased administrative load, one result could be to translate current tensions between scientists and government accountants into the university setting. And there are several procedural issues, such as the way that indirect costs are calculated (currently as a proportion of the salaries and wages included in the grant) that would need to be revised.

The NCR, a body set up two years ago to examine all aspects of research funding, considers that these changes could work. But it urges the need for experiments. The National Science Foundation is already experimenting with post-award aggregation of grants to a selected number of university chemistry departments. The NIH, which supports almost 50 per cent of federally-sponsored university research, is planning to follow suit.

David Dickson

PWR design

UK programme gathers steam

DESIGN work on modifying the Westinghouse pressurised water reactor system to meet British safety standards has begun "in earnest" following a letter of intent issued by the UK Central Electricity Generating Board to the Nuclear Power Corporation late last month.

The NPC is increasing the staff of its light water reactor team from 80 to 170 by the end of September, and plans a total of 400 by the end of 1982. Design staff, who are not nuclear experts as such, are being recruited from engineering fields associated with complicated plant design including piping engineers, quality control draftsmen, power engineers and computer specialists. In addition the NPC is transferring part of its existing staff of 1,200 to PWR work. Included in this number are engineers from the advanced gas cooled reactors located in Hartlepool, Heysham and Dungeness. Two NPC engineers will fly to Pittsburgh next month to work with a Westinghouse licensing group on the transfer of the details of PWR technology to the UK. Five Westinghouse engineers will join the NPC team next month to work on modification of the Westinghouse design to meet UK standards. Technical support from Westinghouse will grow to about 100 professionals by 1982.

NPC staff is concentrating its present efforts on computer simulations of safety procedures and on physical modelling of the layout of the 1100 MW reactor. The design of steam, water, gas and cable runs is to conform with British safety procedures developed through experience in petrochemical plant design.

In conjunction with engineers from the CEGB, the NPC will prepare its modifications of the Westinghouse system which includes a novel "double skin" consisting of two concentric concrete cylinders with the reactor hardware in the inner cylinder and the safety and standby systems in the outer cylinder to meet operator radiation dose standards and plant standby power requirements, and to "relieve burden on the human element". The design work will cost £3.5 million.

The Nuclear Installations Inspectorate says that it expects to receive the CEGB's preliminary safety report — a general outline of the standard safety procedures to ensure reactor safety — within the next few months. This will be followed by a "steady flow" of design information beginning with a safety analysis of the main design followed by fault analyses of particular areas ranging from pressure vessel integrity and the possibility of fast fracture from small cracks (*Nature*, 28 February, p804) to the reliability of used equipment and component failure records. In spite of staff shortages, the NII expects no difficulty in meeting its obligations to evaluate PWR safety.

Approval of the design modifications by the NII by 1982 will be followed by an application by the CEGB for a nuclear site license at the Magnox reactor site at Sizewell. At the same time, the promised public inquiry will also be announced and the safety documentation will be released in accordance with the government's announcement on 18 December 1979 that "principal safety documentation relevant to the initial licensing will be published and made available before the inquiry".

Jo Schwartz

Soviet psychiatry

Mock trial in London

THE second anniversary of the arrest in the Soviet Union of Alexandr Podrabinek was marked in London last week (15 May) by a "public hearing" on the alleged abuse of psychiatry in the Soviet Union. Podrabinek is the author of the *samizdat* treatise "Punitive Medicine" and a member of the organisation known by the cumbersome title of Working Commission for the Investigation of the Misuse of Psychiatry for Political Purposes.

The chief object of last week's hearing, at which Mr Louis Blom-Cooper Q.C. put the case for the prosecution, was to draw attention to the plight of the working commission, only two of whose original members remain at liberty in the Soviet Union. Other members of the commission now arrested include the mathematician Vyacheslav Bahkmin (12 February, 1980) and the physician Leonard Tarnovskii (4 April, 1980). The pharmacist Viktor

Nekipelov, who was a member of the Moscow Helsinki Monitoring Group, had worked closely with the commission until his arrest on 7 December last year.

At last week's proceedings, one of the chief witnesses was Dr Alexandr Voloshanovich, who had been forced to emigrate to Britain in February this year. He told the hearing that he had investigated a total of forty alleged victims of psychiatric abuse before his departure from the Soviet Union, but that in no case had he found "indisputable evidence of the need for hospitalization".

Interest in the West has necessarily centred on the more spectacular cases of alleged psychiatric abuse, such as the hospitalization of Petro Grigorenko for his defence of the Crimean Tartars (and whose cases was simulated in last week's mock trial). Dr Voloshanovich emphasised, however, that the cases which he had investi-

gated were varied, and that in his experience some of those sent to psychiatric hospitals had not given political offence but, rather, had simply been trouble-makers for the system.

Mr Peter Reddaway, co-author of the book "Russia's Political Hospitals", suggested that psychiatric abuse has featured "quite prominently" in recent arrests of those known to have dissident sympathies. Of 200 arrested since last autumn, he said, fifteen have ended up in psychiatric hospitals.

Even so, there are some signs that the Soviet authorities are sensitive to allegations of the misuse of psychiatry in the Soviet Union. When the Royal College of Psychiatrists (London) wrote at the beginning of the year to Dr Andrei Snezhnevskii asking for an explanation of the growing number of reports of psychiatric abuse in the Soviet Union, Snezhnevskii offered no explanation but did resign his honorary membership of the college.

Antarctic ecology

Monitoring krill from land

THIS season's Polish expedition to the Antarctic returned home two weeks ago claiming that it should at some stage be possible to monitor the exploitation of Antarctic krill by observation of the land-based fauna of the Antarctic coast. This is one of the arguments that Polish ecologists will be putting to the forthcoming conference in Paris on Antarctic biomass.

The Polish Antarctic base "Henryk Arctowski" was established in 1976 on King George Island in the South Shetland Islands and can accommodate 70 people in summer, with up to twenty people over-wintering. Given the location of the station, Polish concern with the oceanic ecology of the Antarctic is understandable.

Dr Stansilaw Rakusa-Suszczewski, of the Polish Institute of Ecology and co-ordinator of the biological part of the Antarctic programme, said after the expedition had returned that Poland has no ambition to exploit Arctic krill commercially, but that for the time being at least is concerned only to understand more clearly the somewhat fragile ecology of the Antarctic.

The chief objectives of the biological part of the past season's Antarctic programme were to understand the flow of nutrients off the coast of Antarctica in such detail that marine production could be accounted for. Previous Polish expeditions to the Antarctic have drawn attention in their reports to the way in which marine production is determined jointly by off-shore upwelling and the ex-

change of material between the sea and land surfaces.

Dr Rakusa-Suszczewski now thinks that it will in due course be possible to follow the production and exploitation of oceanic krill, and of other marine animals occupying lowly positions in the food-chain — almost literally low in the oceanic pecking order — simply by maintaining regular counts of the populations of penguins and seals living on the Antarctic coastline.

Marine ecologists will no doubt await the publication of the past season's results before accepting Dr Rakusa-Suszceutski's claim. Penguins and seals are known to be in-shore feeders, and the dependence on what happens in the deep

Antarctic must be tenuous, to say the least of it.

Nevertheless, in strict compliance with the formal terms of science planning in Poland, the Antarctic programme of research is aimed at the solution of an "interdepartmental problem", defined as such because it integrates "environmental and biological research with the objective of understanding the dependence and functioning of part of the eco-system and the inflow of material in the inshore zone of Admiralty Bay".

In case all the subtleties of Antarctic ecology can be worked out only after further painstaking research, Dr Rakusa-Suszczewski is also at pains to emphasise that the past season has produced some practical benefits — the possibility that fish-bile may be a valuable source of cholic acid for the pharmaceutical industry, for example.

Vera Rich

Henryk Arctowski — no krill in sight

CORRESPONDENCE

High book prices

SIR, — It is not just a berserk economy that is to blame for the high price of books. A colleague of mine expressed horror at the price proposed for a hard-back that he had intended for students, and asked why it could not be printed as a paperback. The answer was: "If it sells well then we shall publish a cheap edition". The Russians must be laughing at our marketing.

Yours faithfully,

PHILIP J STEWART

University of Oxford, UK

SIR, — The leader entitled "Are Books too Expensive" (24 April page 649) was a wayward attempt at analysing a problem of great concern to everyone involved in publishing.

We were told that for the price of a skipped lunch we could once walk out of a bookshop with a few titles under our arm; perhaps we could be supplied with the actual year when this was possible. Let us assume it was 1962, before the boom in science publishing. I asked two colleagues who had not read the article how much a cafeteria lunch of say three courses might have cost in 1962; one said 3/-, the other said 2/6. I then checked records for the prices of monographs published in that year; a book of 256 pages cost an average 42/-. To walk out of the shop with one monograph, the author would therefore have had to skip 14 3/- lunches.

How many lunches would the author have to skip now? We have just published a monograph of 256 pages at £15.00 and a simple three course lunch seems to cost around £1.25. The author would actually have to skip two fewer lunches today!

For those who would like a more serious analysis the graph (based on figures supplies by the Publishers' Association) shows how the average price of books published in Britain has risen since 1970. In the same period the UK Retail Price Index has risen a little more, just over 300%. Average earnings have increased by more than the RPI since 1970, but perhaps what the author should be complaining about
is that the average earnings of the book-buying population have probably slipped in relation to the rest of the population.

It is suggested that we should show restraint over symposia and monographs and avoid duplication. Symposia and monographs can, in fact, be published profitably if overheads are kept to a minimum as explained in the *New Scientist* (21 June 1979 page 1013) and the right number is printed, but most

publishers are leaving these to a few companies which concentrate on specialist works. The vast majority of publishers would prefer to sell more copies of fewer titles but as sales of individual titles are decreasing, the response from some publishers has been to publish more titles to maintain turnover. The Soviet Union avoids duplication by controlling publication through central committees. The members of these committees are undoubtedly exceptionally talented but as the author points out, such a system cannot always be right in predicting which book will be essential to the development of a subject.

The real problem for British-based science publishers is that, although they are trying to hold down their prices, the value of the pound abroad is hitting the export market which takes around 60-75 per cent of production. Our books are becoming too expensive in some overseas markets. Our export market has also been weakened by the rise of indigenous publishing houses moving from producing translations of successful English language texts to books written by local authors. Students are prepared to pay more for texts in their first language and aimed specially at their courses. This is a healthy development in publishing as a whole, but it means that the publishers working in the English language can no longer assume that their books are automatically international products and the first choice for students in many parts of the world.

Publishers can adapt to the problem of high selling prices resulting from the high value of the pound abroad by producing abroad; indeed many are already doing so. This however could permanently damage the UK printing industry. The curent wave of redundancies in publishing could be quickly followed by further unemployment amongst printers.

Yours faithfully,

ROBERT CAMPBELL,

Blackwell Scientific Publications
Osney Mead, Oxford, UK

No gas guzzling

SIR, — In your leading article of 17 April about energy conservation, you say that the "Gas Board . . . advertises to encourage us to use more energy".

The fact is we do precisely the opposite — and just what you advocate. Your article is headed "Conserve energy, conserve cash". One of our slogans, widely used, is: "Save Gas, Save Money". Our publicity has plugged an energy conservation line for many years now. Moreover, since early last summer, no promotion of gas or gas appliances has been pursued that would build up gas load at the peak. On the contrary, television advertising about using gas efficiently has appeared throughout the winter months and is being followed by a campaign on similar lines in the national press at present. The efficient use of gas is one of our key objectives.

Yours faithfully,

F W PLOWMAN

Public Relations Department
British Gas Corporation

Responsibility for nuclear weapons

SIR, — Despite rising international tension there is little public debate about Britain's policy on nuclear and other modern weapons, especially in comparison with the impassioned campaigns for and against nuclear energy. And yet while nuclear energy is at worst a

long-term threat to the quality of our civilisation, nuclear weapons could obliterate it in half an hour.

We have lived quietly with this peril for more than twenty years, during which the policy of deterrence has not failed. But there are several disturbing new developments that require urgent discussion, especially by scientists. First, the government's decision to consider producing chemical weapons; second, the government's decision to consider spending £5,000 million replacing Polaris nuclear submarines and missiles with the Trident system; third, the government's reaffirmation that its policy is to offer virtually no protection to civilians in the event of war; fourth, the government's decision to allow cruise missiles to be stationed in Britain; fifth, the increased accuracy of guidance systems (which could tempt the Russians or Americans into considering a first strike against each other's missiles).

The scientific community must play an important part in the extensive discussions that these ominous developments ought to provoke. In particular we should put under close scrutiny the activities of our colleagues who carry out weapons development. Lord Zuckerman has argued first, that their technical innovations have created a new situation, undermining deterrence by making all-out war a seriously-considered policy option, and, second, that the implementation of new weapons systems is often at the instigation of scientists rather than of the military. No longer should it be claimed as in the Second World War that military scientists are helping their side to win, nor, as in the 1950s that they are building up an effective deterrent. Instead, it should be recognised that the contribution of scientists to warfare has entered a third phase, in which their prolific inventive capacity is itself a powerful destabilising influence.

The consequences of the arms race continuing unchecked are so dire as to make it imperative for us to overcome the paralysing hypnosis induced by our sense of helplessness as individuals. As a small beginning we invite scientists to take the following steps:

1. To oblige those of our colleagues who devise and advocate new weapons of mass destruction to stand up and justify their work (as their counterparts in the nuclear energy industry are having to do).

2. To inform our students (and ourselves!) of the far-reaching and complex relationship between military technology and progress in 'pure' science.

3. To initiate informed discussion on weapons development in our various institutions and professional bodies and to make our own view clear. Those opposed to further weapons development might consider discouraging students from applying to enter military research establishments.

4. To support currently faltering international attempts towards arms control.

5. To promote public discussion by making MPs aware of our fears and encouraging them to play an active role in forming sane weapons policies.

NEWS AND VIEWS

The Cretaceous-Tertiary boundary event

from Finn Surlyk

SIXTY-FIVE million years ago a major crisis hit the flora and fauna of the earth. In stratigraphic terms this took place at the boundary between the Cretaceous and Tertiary systems. Evidence for the crisis lies in the more or less simultaneous extinction of major groups of animals and plants including such characteristic elements of Mesozoic life as the dinosaurs, the great marine reptiles, the flying reptiles, the ammonites and belemnites, many bivalve groups, and major groups of marine phyto- and zooplankton[1,2]. It has been estimated that as many as 75% of Cretaceous species may have been eliminated.

Searching for the cause of this event has been a favourite pastime for a large number of scientists and a great number of hypotheses have been put forward. Some observations suggest a catastrophic mechanism whilst others are indicative of more gradual processes[1-3].

In the last few years the catastrophists have dominated the scene. The main reason for this is the extremely abrupt wholesale extinction of major groups. This is well known from the type area of the lowermost Tertiary, Danian Stage in Denmark[4,5] from several sections in Spain[6], from the Italian Apennines[7], and from many holes of the Deep Sea Drilling Project[8,9].

The catastrophists of today seem to have focused on two major hypotheses. The first one is of terrestrial nature and comprises spill-over of brackish water from an isolated Arctic Ocean at the time of opening of the Greenland Sea — Norwegian Sea passage by sea-floor spreading[8,10]. Thierstein and Berger[8] supported this theory by carbon and oxygen isotope data, while Gartner and Keany[10] used nannoplankton from North Sea chalk to support the "spill-over" hypothesis. In the latter case an isolated occurrence of a 'Danian' nannoflora was

found in a core 55 m below the supposed top of the late Cretaceous, Maastrichtian stage. This was taken to suggest that 'Danian' coccolithophores and planktonic foraminifers developed during late Cretaceous times in an isolated Arctic Ocean having a greatly reduced salinity. An initial, temporary opening of the Greenland Sea thus accounts for the lowermost occurrence of "Danian" coccoliths in the late Maastrichtian.

The North Sea section was, however, reinterpreted by Perch-Nielsen *et al.*[5] and by Watts *et al.*[11] who clearly demonstrated that the Maastrichtian-Danian boundary actually occurs below the lowest 'Danian' interval and that the overlying 55 m of Maastrichtian chalk actually represents slide material redeposited in Danian time. While this work certainly invalidates the data base for the Gartner-Keany hypothesis, it does not necessarily eliminate the spill-over hypothesis.

The second major catastrophic hypothesis is of extraterrestrial nature involving the influence of a supernova, meteorite or comet. While this idea is not new it has had a considerable revival in the last few years due to the discovery by Alvarez *et al.*[5] of anomalously high levels of iridium at the Cretaceous-Tertiary boundary in several sections near Gubbio, Italy. Ir in crustal rocks is typically 10^{-3} of solar system levels, so high Ir could indicate an influx of extraterrestrial material. Ir isotope measurements show less than a 2% difference from the terrestrial Ir ratio suggesting that the Ir came from a solar system source, not a supernova.

The same anomalous trace element enrichment, especially of iridium and osmium at the time of extinction was recorded by Smit and Hertogen[5,6] (this issue of *Nature*) from an almost complete sequence across the Cretaceous-Tertiary boundary in Caravaca, SE Spain. This was

taken to support the idea of a large meteorite collision.

Hsü, also in this issue of *Nature*, has used the extinction and trace element data from Gubbio and Caravaca to advance an extreme theory[12] that suggests the extinction of the large terrestrial animals was caused by atmospheric heating during a cometary impact. Poisoning by cyanide released by the fallen comet and a catastrophic rise in the calcite compensation depth in the oceans are separately proposed as the main agents responsible for the extinction of the calcareous marine plankton. Several tests are possible for this hypothesis. First, where is the crater? Hsü assumes that the meteorite fell in the ocean, and since much of the Mesozoic ocean floor has disappeared by subduction, the crater may have vanished. The instantaneous extinction of the large terrestrial animals offers another test possibility. Where are all the accumulations of both vertebrate and invertebrate skeletons at the boundary? It may of course be argued that some of the terrestrial skeletons were destroyed by burning, but, if found, such fossel populations should have a characteristic age distribution indicating mass-mortality of the whole population.

A very recent paper on the Gubbio sequence by Wezel[13] should dampen the enthusiasm of the catastrophists.

The key geological section for the catastrophists is situated at Bottaccione near Gubbio in the Italian Apennines. It is generally interpreted as an essentially complete sequence of Middle Cretaceous to Palaeocene calcareous, pelagic sediments[14]. Palaeomagnetic studies of the Upper Cretaceous and Tertiary parts have yielded a sequence of magnetic polarity zones, which are said to correspond

Finn Surlyk is in the Geological Museum of Copenhagen University.

precisely with the marine magnetic polarity profiles. They are dated by foraminifera[7], and the section is proposed as a magnetostratigraphic type section[15]. The Bottaccione data have furthermore been used to recalibrate the existing magnetic time scale and thus to revise the oceanic spreading rates. The tectonic rotation of the Italian peninsula as an independant microplate or as part of the African plate is clearly seen in these magnetic data. Finally, trace element anomalies mentioned above have been of tremendous importance in the discussion on the late Cretaceous extinction event.

The exact nature of the sequence has thus formed the basis for the catastrophist's far reaching conclusions. Data published so far on the sedimentology of the critical strata are sparse and mainly of lithostratigraphical nature[14] and can not provide the basis for a detailed interpretation.

Wezel's recent detailed study[13] of the sedimentology of the critical sequence is thus of fundamental importance. This is particularly the case as Wezel in his introduction states that "The formation turned out not to be the product of a long and continuous 'gentle pelagic rain' and also the classical and type-biostratigraphic zones were found to contain younger reworked foraminifera" and ". . unfortunately things are not as simple as thought by previous researchers".

According to the detailed and convincing observations by Wezel a lot of the presumed 'pelagic' deposits are calciturbidites resedimented from currents flowing from the east. Stratigraphic changes of magnetic properties at Gubbio seem crudely to match local variations in bed thickness. This certainly rules out the possibility of using the section as a magnetostratigraphic type section for the Upper Cretaceous and Palaeocene. Finally, sedimentologic evidence suggests general reworking of microfossils with very few indigenous forms. This taken together with the very poor fossil preservation in the sequence and the extremely low macrofaunal diversity detracts very strongly from the stratigraphic value of the once celebrated section. Wezel's paper is so detailed that the burden of proof now rests on his opponents[7,14,15].

One feature of the Gubbio section still has to be explained; namely the anomalously high iridium and osmium contents. Since the relevant analytical

techniques are quite cumbersome, relatively few determinations of Ir and related trace elements are to be found in the literature on sedimentary rocks. The question thus arises: What do we know of the amount of iridium present in other parts of the sedimentary record? How many analyses have been undertaken and how many is it necessary to undertake before one can safely claim than an occurrence is anomalous?

It thus seems that we are back again where we started and the end-Cretaceous extinction event still presents one of the major examples of the 'Vogt-Holden Effect[5]': "New data, regardless of reliable source of high quality, have scarcely ruled out any past theory, but have fueled the promulgation of newer and even more outlandish proposals". □

Kaon-Nucleon physics

from David Miller

MESON-NUCLEON interactions are at the core of the old-fashioned strong-interaction theory of elementary particles and, although we now have a new-fangled strong-interaction theory of quarks and gluons (quantum chromodynamics 'QCD' see *Nature* **279**, 479; 1979) the structure of the meson-nucleon scattering amplitudes still has to be studied by the old techniques. The relationship between the two theories is not very direct, but one important source of data for those who try to build hadrons (strongly interacting particles) from quarks is the spectrum of meson-nucleon resonances. These resonances appear as poles in the complex scattering amplitudes and it has been the task of experimental physicists for over twenty years to measure scattering cross-sections and polarisations at a wide range of angles and energies in order to reconstruct the amplitudes. Since the data is always limited in both coverage and precision the old-fashioned theory developed a set of mathematical tools, particularly dispersion-relations, which impose strict constraints on the analyticity and continuity of the partial-wave scattering-amplitudes. Reports were presented by Koch (Karlsruhe, Helsinki) and Cutkosky (Carnegie-Mellon, Lawrence Berkeley Lab.) on the latest results of fits to the pion-nucleon data. The general mutual agreement of these fits was impressive. Unanswered questions remain. For instance, it is not clear whether the "minimum multiplets" postulated for the quark-structure of resonances can survive; only negative-parity {70} and positive-parity {56} representations in SU(6) have so far been firmly established but Cutkosky reported a number of awkward new candidates which are hard to fit in. Nevertheless, the major structures in the lower partial waves are clear and such basic dynamical quantities as the πNN coupling constant and the "sigma term" can be quoted with some precision (e.g. $g^2_{\pi NN} = 13.9 \pm 0.36$ — Samaranaika *J. Phys. G.* **5**, 657; 1979).

The structure of the kaon-nucleon and antikaon-nucleon amplitudes is by no

---

A workshop on low and intermediate energy kaon nucleon physics was held at the University of Rome, March 24-29 1980.

---

means so clear. Oades (Aarhus) reviewed the partial wave analyses and a number of speakers, especially from the host group, discussed the dispersion-relations, the zeros of the scattering amplitudes and the sigma terms. A few important features seem to be settled. The $\overline{K}N\Lambda$ coupling has been determined by a number of techniques which give different weight to different parts of the data. Queen (Birmingham) reviewed these results, which mostly give values for $g^2_{\overline{K}N\Lambda}$ between 14 and 17, in good agreement with the SU(3) prediction that $g^2_{\overline{K}N\Lambda} \simeq 1.08 \times g^2_{\pi NN}$. The ispin zero triplet p-wave in kaon-nucleon has a resonance-like behaviour in most fits, but it is generally agreed that it can be explained as a 'woolly cusp' a combination of an attractive potential and the opening up of the inelastic channels. New data were presented on K^+ neutron polarisation from groups working at KEK (the new Japanese proton-synchrotron) and at NIMROD (the retired British proton-synchrotron). Preliminary fits to the NIMROD data by the Queen Mary College — Rutherford group have shown good agreement with B. R. Martin's existing fit, but the KEK data did not seem so closely compatible with previous fits. These are preliminary results from both groups and it will be interesting to see how their presentation develops after the long corridor-discussions between their spokesmen (Takasaki from KEK and Watts from Queen Mary College). But, whatever the outcome, it seems that there is no need to strain the quark-models in order to account for an exotic (5 quark) K^+— neutron resonance.

The antikaon-nucleon resonance spectrum is still quite fluid. Different fits to the data disagree in quite low partial-waves and there is even a major puzzle, the Λ (1405), below the $\overline{K}N$ threshold. Because the mass of a K^- and a proton (1432 MeV/c^2) is considerably higher than that of a pion and a lambda-hyperon (1251 MeV/c^2) or a pion and a sigma-hyperon (1327MeV/c^2) there can be exothermic $K^-p \rightarrow (\Lambda\pi$ or $\Sigma\pi)$ transitions even from K^- interacting at rest. Experiments in which $\Sigma\pi$ states are produced in association with other final-state particles have

100 years ago

A remarkable phenomenon was observed at Kattenau, near Trakehnen (Germany), and in the surrounding district, on March 22. About half an hour before sunrise an enormous number of luminous bodies rose from the horizon and passed in a horizontal direction from east to west. Some of them seemed of the size of a walnut, others resembled the sparks flying from a chimney. They moved through space like a string of beads, and shone with a remarkably brilliant light. The belt containing them appeared about 3 metres in length and 2/3 metre in breadth.

At Paris a Society "contre l'abus du tabac" has been formed, which intends to combat the excessive indulgence in smoking which has of late become the fashion in almost the whole of Europe. The Society offers various prizes for treatises on the human health and the dangers it is subject to from excessive use of tobacco.

The Archaeological Society of Athens has purchased about half the village which stands upon the ruins of the Temple of Eleusis. The Society intends building new dwelling-house in another part, and to begin with excavations as soon as the present inmates of the village have moved.

The astronomer, Herr Rudolf Falb, well known through his theory of earthquakes, has returned from his South American exploring tour, which extended over a period of more than two years. In his researches he was led in the direction of ethnography and linguistics, and believes that he has made interesting discoveries regarding "the original language of the human race."

from *Nature* **22**; May 20, 64-66; 1880.

---

shown a clear peak in the $\Sigma\pi$ mass-spectrum at 1405 MeV/c^2. Such peaks are normally attributed to resonances, and the SU(6) theory has a place for one such resonance. But 1405 MeV/c^2 is so close to the physical $\bar{K}N$ region that the presence of a resonance should have an effect on $\bar{K}N$ scattering at the lowest energies. An elegant K matrix formalism has been developed for dealing with these processes. A. D. Martin (Durham) gave an up-date on his fit to the formalism, using dispersion relation constraints to eke out the sparse data on low energy K$^-$p collisions. Dalitz (Oxford) agreed with Martin that there was no apparent need to invoke a quark-model resonance to explain the 1405 bump. It could be produced by non-singular meson-baryon (i.e. antikaon-nucleon or pion-hyperon) interactions, complicated in this region by cross-couplings between the channels.

There is great interest in the Λ (1405) question among physicists studying strange-particles in complex nuclei. Here the binding energy brings down the effective nucleon mass, and Fermi motion adds further complications. Dover (Brookhaven) gave a review of the work that has been done on hyperfragment formation by pion and kaon beams. Little has changed since last year's hyperfragment and K$^-$ conference in Warsaw (proceedings to be published in *Nucleonika*) but he illustrated how the new generation of precision spectrometer experiments is extending nuclear structure studies into this intriguing field. Batty (Rutherford) reviewed kaonic X-ray studies. On heavy nuclei no one knows how the observed level-shifts and line-broadenings should be related to low-energy kaon-nucleon processes, but his collaboration (working at NIMROD) has set a puzzle by measuring a line which may be due to the 2p to 1s transition in antikaonic-hydrogen. The line is narrow and is not shifted significantly from the position predicted for it with a

Coulomb potential alone. This suggests a very weak antikaon nucleon coupling at threshold (1432 MeV/c^2), contrary to the results of all the fits, including A. D. Martin's. Kumar (Mc Master) claimed that he could fit the Λ (1405) as a resonance and match the weak coupling required by the kaonic-hydrogen result, but it was not clear if his model could be made consistent with all of the available low energy $\bar{K}N$ data. If the properties of the kaonic hydrogen X-ray line are confirmed by new experiments to be done at CERN, then those of us working on low energy antikaon-nucleon collisions will have to devise totally new techniques to study the scattering cross-sections at lower energies than can be reached at the moment. We had thought that our latest results (Durham, Brussels, Warsaw, UCL collaboration) were removing the remaining anomalies and agreeing well with A. D. Martin's fit, but there are still many poorly measured channels, particularly K$^-$p $\rightarrow$ $\Sigma^\circ\pi^\circ$ in which the Λ(1405) should be important, and the K matrix parametrisation remains under-constrained. $\square$

Oil geology in China

from A. Hallam

As befits a country with an impressive tally of early discoveries, there is a record of 'fire in the swamp' (evidently marsh gas or methane) in the ancient Chinese Book of Changes, written in the 11th Century BC. In the early 12th century a gas well over a kilometre deep was drilled in Sichuan Province, but the beginning of the Chinese petrolem industry dates from 1907, when a foreign crew employed by the government of the Qing Dynasty discovered Yanchang oilfield in Shanxi Province.

For most of the first half of this century oil production remained at a very modest level but since the founding of the People's Republic there has been a considerable expansion of both exploration, with the

discovery of over 160 oilfields, and production, which last year reached 106 million tons, putting China among the top dozen oil producing countries in the world. The capital city of Beijing (Peking) was thus an appropriate place for an international conference on petroleum geology.*

A measure of the importance attached to the conference by the Chinese is that the participants were granted an audience in the Great Hall of the People by Vice Premier Kang Shi En, who exhibited a considerable knowledge of the petroleum industry. He looked forward to a huge increase in production to help promote the so-called four modernisations (Agriculture, Industry, Science and Technology, and National Defence).

While the conference lectures ranged far and wide the greatest interest of the overseas participants was obviously in the Chinese contributions, because Chinese oil geology has been hitherto largely a closed book to the outside world. Three matters of especial interest may be singled out. Firstly, virtually all the oil and gas has been generated in source rocks of continental origin, and the Chinese were manifestly proud at having confounded those pundits of an earlier era who had consistently argued that significant quantities of hydrocarbons could only be generated in marine deposits. Thus the giant Daquing Oilfield in the Songliao Basin of Manchuria, which accounts for half the current production of the whole country, occurs in a region which developed as a faulted depression in Jurassic times, long after the Palaeozoic seas had retreated. By the mid Cretaceous it became established as an open lake basin, persisting into the Tertiary, in which a great thickness of organically-rich clays was deposited. Wedges of fluvial and deltaic sands in the clays, combined with anticlinal structures, provide an excellent combination of reservoir, source and cap rocks with structural traps.

A second point of major geological interest is the occurrence under the North China Plain of so-called 'buried hill' oilfields. Huge thicknesses of shallow-water carbonates of Proterozoic to Ordovician age were subjected to extensive karstification during a lengthy period of emergence from the late Palaeozoic to the early Mesozoic, with the development of numerous small and large cavities. Subsidence under tension of a zone extending SSW from Manchuria commenced in the late Mesozoic and continued into the Tertiary. The old karst landscape was deeply buried under thick Tertiary lacustrine clays and sands. The cavities in the ancient carbonates have proved to be excellent oil reservoirs, the oil having migrated laterally from Palaeogene clay source beds, as proved by the presence in the oil of spores and pollen of that age.

David J. Miller is in the Department of Physics and Astronomy, University College, London.

A. Hallam is Lapworth Professor of Geology in the University of Birmingham.

Thirdly, the Chinese exhibited a substantial knowledge of the scientific literature and technology of the West, all the more impressive bearing in mind the setbacks of the Cultural Revolution. In fields as diverse as sedimentological facies modelling and organic geochemistry they demonstrated that they had kept well abreast of modern developments. Their geophysicists, furthermore, are well ahead of the Russians in having adopted modern digital methods of seismic data processing.

Perhaps the sphere in which we in the West can offer the most help is in advice on organisation. At present the Chinese geologists and geophysicists operate independently. Efficiency could be vastly improved by integrated team efforts, for instance in the new and rapidly advancing field of seismic stratigraphy. Furthermore, it is rather strange that, while the Oil and Gas Corporation is responsible for the great bulk of the exploration and production efforts, the Ministry of Geology (effectively the Geological Survey) operates quite independently its own exploration programme both onshore and offshore.

One of the highlights of the meeting was a visit to the Renqiu Oilfield 160 km south of Beijing, which produces some 10 million tons per year from buried-hill reservoirs. This was the first-ever visit by foreigners and was accompanied not only by Chinese television camera crews and representatives of the Peoples Daily but an odd-looking assemblage of foreign pressmen, who seemed more interested in the sociology than the science or technology. The American and European

oil geologists were amazed to learn that this oilfield is quite typical in possessing its own research laboratory, equipped with the most modern petrological and geochemical apparatus. Even the microfossils are identified, as it were, on the spot. Some scepticism was expressed about how even a major oilfield could keep the laboratory workers usefully employed for long periods in more than routine monitoring.

Intensive exploration for hydrocarbons has so far been largely restricted to the eastern part of the country, although large gas discoveries in Sichuan have made the province self sufficient in that commodity. While there are some promising prospects in the vast region of Xinjiang, notably inthe Tarim Basin, the greatest hopes in the immediate future are in offshore areas. The Chinese have for some time been operating drilling rigs in the Gulf of Bohai, and extracting oil from deeply buried, tilted fault blocks created by tensional collapse in the Tertiary and reminiscent of the major oil-producing structures in the North Sea. Within the last year they have invited a number of major North American and West European companies to shoot seismic lines in the Yellow and South China Seas. The results will be analysed by Chinese specialists, who will make recommendations to the Ministry of Petroleum Industry. Representatives of the Ministry will shortly be meeting with their opposite numbers in Norway and the United Kingdom, presumably to obtain advice from those experienced in granting offshore concessions. Thus we may look forward to the possibility of companies like Exxon and B.P. drilling in Chinese water, a measure of the modern pragmatism that should cause the Gang of Four a further turn in their metaphorical grave. □

sequences of integral membrane proteins with their largely hydrophobic composition has required the development of special procedures, different from those currently used for water-soluble proteins. The complete sequence of the 247 amino acids of bacteriorhodopsin was found by Ovchinnikov and colleagues (*FEBS Letters* **100**, 219; 1979) and large portions have been confirmed by Gerber *et al. (Proc. natn. Acad. Sci U.S.A.* **76**, 227; 1979) and Walker *et al. (Nature* **287**; 1979). As expected the polypeptide chain has long tracts of hydrophobic residues that represent the transmembrane helices; these were used by Ovchinnikov in a preliminary attempt to fit sequence to structure. However the methods used by Henderson and his colleagues are somewhat more sophisticated and warrant detailed consideration.

An important preliminary to combining the sequence and the structure, was to find the molecular boundaries for a single bacteriorhodopsin molecule. This could be done because detergent treatment of the purple membrane produces *in vitro* a new two dimensional crystal form of bacteriorhodopsin. Electron diffraction analysis of this form in projection (Michel, Oesterhelt & Henderson *Proc. natn. Acad. Sci. U.S.A.* **77**, 338; 1980) shows an identical protein structure to that observed in the purple membrane, confirming the original molecular boundary.

The first step was then to locate the seven helical segments in the sequence. This was done by making use of the known points of proteolytic cleavage which must occur at surface residues, and of the similar lengths of the seven transmembrane helices, which on energetic grounds must be largely hydrophobic. In the assignment proposed by Henderson there are 27 charged residues on the membrane surfaces and 9 buried in the interior of the membrane. The neutralization of charge by pairing these 9 buried residues becomes a major determinant in the structure prediction.

The second step was to attempt to identify the seven helical segments in the sequence (labelled A to G) with the seven helical segments in the image (labelled 1 to 7). Because the orientation of the protein in relation to the inner and outer membrane surfaces had already been established, there are 7!, or 5040, ways of combining the predicted and observed helices. To reduce this number to more manageable proportions, Henderson and his colleagues filtered the models sequentially through a number of criteria, a procedure broadly similar to that currently used in predicting the tertiary structures of proteins. The first filter was concerned with minimizing the lengths of the six interhelical loops, and disallowing loops that crossed over one

Predicting a membrane protein

from Colin Blake

ONE of the most elegant and original structural studies of a biological system in the recent past has been that of Henderson and Unwin (*Nature,* 257, 28; 1975) on the 'Purple Membrane' of *Halobacterium halobium.* As the protein component of the membrane, bacteriorhodopsin, is a single molecular species organized into a two-dimensional crystalline array they were able to use electron diffraction to produce a three-dimensional low resolution image of the membrane protein *in situ.* Bacteriorhodopsin was revealed as an integral membrane protein composed of a cluster of seven almost parallel helices oriented perpendicular to the membrane surface.

This low resolution image was fascinating but to understand the general principles of membrane proteins and the

function of the purple membrane as a light-driven proton pump a model with atomic detail was required. This could be achieved either by increasing the resolution in the electron diffraction pattern, or by using the existing image as a basis for predicting the structure. The latter approach has been successfully used by Engelman, Henderson, McLachlan and Wallace (*Proc. natn. Acad. Sci. U.S.A.* 77, 2023; 1980). Although less direct than extending the resolution of the image, prediction of the bacteriorhodopsin structure brings together a number of principles of protein and membrane structure and perhaps represents the more fruitful direction for future work on membrane systems.

Knowledge of the amino-acid sequence of bacteriorhodopsin was essential to either approach. Determination of the

Colin Blake is in the Laboratory of Molecular Biophysics, Department of Zoology, University of Oxford.

another on the same side of the membrane. This reduced the number of models to 405 which were rank ordered according to the total length of the interhelical loops. These models were then subjected to the test that the nine buried charged residues should geometrically be able to form ionpairs. This reduced the number of models to 405 which were rank ordered according to the calculated electron densities of the seven predicted helices with the integrated scattering densities of the helices observed in the image of the purple membrane protein. In the image helices 1 and 5 have significantly lower scattering densities than the other five. Of the predicted helices, helix D with five glycines and no large hydrophobic residues has the lowest calculated electron density, while helix A also has much lower density than the other five. This test revealed that the model with the shortest interhelical loops and the

geometry required to neutralize the charges of the buried residues, was also one of the few to meet the helix scattering criterion.

Not only does this one model of bacteriorhodopsin emerge as by far the most probable, it also possesses a number of features that seem suitable for a proton pump. The buried charged residues form one or more networks of ion-pairs through which protons may be able to jump. The retinal group probably lies near the surface of the membrane with its ring possibly buried near an aspartic acid residue. Finally adjacent helical segments in the sequence are also adjacent in the structure suggesting a particular simple folding pathway.

Confirmation of this model will be necessary, but at present it must be regarded as easily the best view we have of the structure-function relationship in a membrane protein. □

Dual polarization radar

from Thomas A. Seliga

EVER since the development of radar in the late 1930's and early 1940's, meteorologists and hydrologists have waited for the time when radar's full capabilities could be exploited for research and field operations. Progress from remote storm detection to assessment of storm characteristics has continued to the point where we can now estimate the drop size distributions of rainfall in a scattering volume (and, therefore, water content or rainfall rate), the nature of the hydrometeors producing the radar signal (whether ice particles or rain) and the bulk motion of the hydrometeors. In this issue of *Nature* Hall *et al.*[1] clearly demonstrate the first two kinds of measurement through use of the differential reflectivity (Z_{DR}) linear polarization scheme first proposed by Seliga and Bringi[2,3] for rainfall measurements. Pulsed Doppler radar techniques have also developed rapidly over the last fifteen years,[4,5,6] producing dramatic advances in our understanding of storm dynamics. This technique has been recently reviewed[6],so here the impact that polarization radar measurements like those of Hall *et al.* might have in a number of areas of meteorology and hydrology will be examined. It should be noted that Canadian scientists have also developed the use of circular polarization techniques and that their results too, are of great potential importance[7,8,9].

Hydrology

The accuracy of the Z_{DR} technique for measuring rainfall is expected to be of the order of 30% for a single observation at a

single range gate. Since this measurement can be made within around a 200 ms time interval, and corresponds typically to an areal coverage of less than 0.5 km^2 for modest size radar antennas at S-band wavelengths, large areal surveillance (of the order of 35,000 km^2) with high spatial and temporal resolutions of rainfall will become possible.

The resultant benefits to hydrology are many: flash flood forecasting should become more reliable; study of the evolution of rainfall in different meteorological regimes and storm types will be possible, leading to improved description and classification of storms; understanding of topographical influences on rainfall should improve; watershed and stream flow modeling should progress; rainfall in semi-arid and arid lands should be more readily monitored; and, in future, hydrologic structures should be improved as a result of more accurate, detailed information on rainfall.

Cloud Physics

Possibly the most important application of Z_{DR} in meteorology will be in studies of the organization and structure of clouds and precipitation on the mesoscale and microscale.[10,11,12] The ability to measure rainfall accurately from a single radar site independent of raingauge calibration, to follow the evolution of rainfall and its drop size distribution in space and time, and to accumulate and display data in real time, should provide new insights into our understanding of precipitation processes. Quantitative data of this type, when combined with Doppler data, will test the credibility of numerical cloud models and further their development. The second very important result of Hall *et al.'s* measurements is the ability to discriminate

clearly between ice and water phase hydrometeors; this will lead to improved understanding of cloud development and precipitation formation. Important data on melting, drop breakup, and the development of raindrop size distributions, should also result from such measurements.

Climatology

The development of the Z_{DR} radar technique, which can provide accurate rainfall measurements over large areas, is very important for climatological studies, particularly within the context of the World Meteorological Organizations's World Weather Watch (WWW) and Global Atmospheric Research Programme (GARP) and their subprograms.[13,14]. For example, the recently conducted GARP Atlantic Tropical Experiment (GATE) and Monsoon Experiment (MONEX) would have benefited greatly had this radar capability been available and employed. Also, use of radar for ground truth measurements of rainfall intensity and cloud structure, particularly over the oceans, should aid in the development of reliable satellite methods of estimating rainfall over remote regions of the Earth's surface. Such data is indispensible for global weather studies and validation of general circulation and climate models. Moving to smaller scales, it is apparent that regional rainfall statistics should be largely improved as radars having polarization capability become operational.

Weather Modification

Whether human intervention can influence atmospheric conditions to enhance precipitation by significant amounts remains the foremost question in weather modification.[15] The importance of this problem is reflected by the Seventh World Meteorological Congress (1975) recent approval of a WMO Weather Modification Programme and Precipitation Enhancement Project (PEP).[16] Again, the importance of using the dual polarization radar technique in such programs becomes evident. Accurate rainfall measurements with high spatial (1 km^2) and temporal (tens of seconds)

resolutions over large areas (35,000 km²) and hydrometeor phase detection, are essential ingredients to any such effort. Hall *et al.*'s RHI grey scale plots of Z_{DR} and reflectivity and drop size distribution measurements show how the Z_{DR} radar might contribute to weather modification experiments. Indeed, one can contemplate using such radar data in case studies of seeded storms as a determinant for testing weather modification techniques. Whether this approach can supplant statistical methods of evaluation deserves serious attention. Another exciting role for dual polarization measurements in weather modification might arise from using Z_{DR} signatures of tracers released with seeding agents. Possible tracers include specially designed chaff and surfactants which significantly affect raindrop shape.

Other Applications

As noted by Hall *et al.*, the polarization radar should also have important applications in communications and erosion studies. Understanding the variability and characteristics of hydrometeors along terrestrial and satellite radio propagation

paths is required for systems design while erosion, both of airborne vehicles and land surfaces, depends strongly on drop size distribution. Other possible applications might include studies of precipitation scavenging of airborne particles and pollutants, hail detection, detection and classification of severe storms, and aviation radar for detecting supercooled water droplets, a precursor to possible aeroplane icing conditions.

As more radars, modified to perform dual polariztion Z_{DR} measurements, become available, many of the above applications will be critically tested. The relative simplicity of the method and recent advances in high-power, microwave switching technology should enable many existing radar facilities to be modified at modest cost. This will offer many scientists opportunities to explore these ideas during this decade. The first measurements have produced dramatic results. Fulfilling all the hoped for applications is perhaps asking too much; being able to perform reliable, continuous and accurate measurement of rainfall would be enough! □

its effector in Ca^{2+} mobilising systems are not the protein components of the cell membrane but the phospholipids. M. J. Berridge (University of Cambridge) supported the idea that changes in a minor anionic species of phospholipid, phosphatidylinositol, might have this intermediate role. Several years ago it was pointed out that an enormous range of Ca^{2+} mobilising hormones also stimulate breakdown of phosphatidylinositol by a phospholipase C (Michell *Biochim. Biophys. Acta* **415**, 81; 1975). Berridge's experiments on fluid secretion by blowfly salivary glands demonstrate a correlation between the movement of Ca^{2+} ions into cells and the breakdown of phosphatidylinositol. However, some recent evidence in other tissues suggests that phosphatidylinositol breakdown may not have this intermediary role in Ca^{2+} mobilisation (e.g. Cockcroft *et al. FEBS Lett.* **110**, 115; 1980) although this may not preclude its having a different function — for example in the termination of the response.

A quite different phospholipid change was reported by J. Axelrod (National Institute of Health. Bethesda) in some of the cell types which are also known to show a phosphatidylinositol response. In these cells phosphatidylethanolamine can be converted by successive methylation to phosphatidylcholine, and this is degraded by a phospholipase A_2 to release fatty acids. In the systems examined a rapid response to stimulation has been seen. Unfortunately only a limited number of cell types have so far been studied, and it is likely that all of these cells synthesize prostaglandins from arachidonic acid as one consequence of cell stimulation. The observed phospholipid changes may thus be a means to generate the necessary fatty acid precursor from arachidonate-rich phosphatidylethanolamine; an effect specific to the cell types examined rather than a general process during receptor function.

There is yet another possibility. W. Trautwein (University of Saarland, Germany) described measurements of conductance changes associated with a muscarinic receptor in heart. The results showed considerable similarity to comparable experiments with the much more rapidly responding nicotinic cholinergic receptor (D. Colquhoun, University College, London,). It is generally assumed that the nicotinic receptor molecule is itself an ion channel (in this case for Na^+), although a completely convincing demonstration of that *in vitro* has still not been achieved. A possible implication is that for Ca^{2+} mobilising systems such as the muscarinic receptor there is no biochemical intermediate at all.

As yet the molecular understanding of

Drug receptors and their effectors

from Jonathan Bennett

How does hormonal information enter the cell? Are there intermediate biochemical events between binding of hormone to a cell surface receptor and the change in the cytoplasmic concentration of a second messenger? This was one of the problems pinpointed by the organising chairman (N.J.M. Birdsall, National Institute for Medical Research, London) at the recent Biological Council Symposium* on "Drug receptors and their effectors".

The best understood receptors in this respect are those whose cellular effects are mediated by the second messenger molecule, cyclic AMP. A few years ago evidence from various approaches forced the conclusion that the hormone receptor and its effector (the cyclic AMP-synthesising enzyme, adenylate cyclase) were separate molecular entities. It is now clear that a third protein component, a GTP binding protein, is involved (for a recent review, see Rodbell *Nature* **284**, 17; 1980). M. Schramm (Hebrew University of Jerusalem, Israel) described his experiments using a cell fusion technique to demonstrate that the GTP-binding protein acts as an intermediate between the hormone receptor and its effector. Binding of a hormone to the receptor causes the GTP-binding protein to change to an "active" form which in turn stimulates the

Jonathan P. Bennett is in the Department of Experimental Pathology, School of Medicine, University College, London.

enzymatic activity of adenylate cyclase.

One consequence of this intermediate step between receptor and effector in the adenylate cyclase system is that it may allow other hormones and drugs to interact to modulate adenylate cyclase activity. A. J. Blume (Roche Institute, Nutley, US) described how binding of opiates to mouse neuroblastoma cells results in an inhibition of adenylate cyclase. The binding of opiate agonists to these cell membranes is enhanced by GTP, and it is a reasonable hypothesis that the opiate receptor interacts with the adenylate cyclase system at the level of the GTP-binding protein.

There may be a similar interaction at the muscarinic cholinergic receptor (E. C. Hulme, National Institute for Medical Research, London) where GTP also interacts with agonist binding to isolated membranes. The effector molecule for this receptor is presumed to be a plasma membrane channel which allows Ca^{2+} ions to enter the cell — and certainly muscarinic responses belong to the large class of hormone effects which are mediated by an increase in intracellular Ca^{2+} as a second messenger. Does the interaction of GTP with muscarinic agonist binding imply that another GTP-binding protein acts as an intermediate in Ca^{2+} mobilising systems? This is a new possibility in a field where the molecular events following receptor activation have eluded critical analysis.

Alternative candidates for the intermediate step between the receptor and

the activation of cells by hormones which use intracellular Ca^{2+} as their second messenger lags far behind our knowledge of the adenylate cyclase system. The principal reason for this is technical — no one can yet measure changes in membrane permeability in a test tube in such a way that adenylate cyclase activities can be measured. Only when such an analysis is possible can biochemical techniques be applied. □

Platelet-activating factor

from Noel J. Cusack

WHEN IgE-sensitized rabbit leucocytes are challenged *in vitro* with antigen they secrete an extraordinarily potent, soluble, low molecular weight platelet-activating factor (PAF), which causes platelets to change shape, aggregate and release their granule contents. PAF is also released *in vivo* into rabbit plasma during the development of IgE-induced systemic anaphylactic shock and appears to be an important mediator of inflammation and allergic responses. Platelet activation by PAF is independent of arachidonic acid metabolites or released ADP. Endogenous PAF from platelets may account for that portion of thrombin and calcium ionophore induced platelet aggregation which is not prevented by blocking the ADP and arachadonic acid mechanisms, but is diminished by phospholipase A_2 inhibitors. Recent work by two independent groups (Demopoulos, Pinckard & Hanahan *J. Biol. Chem.* **254**, 9355; 1979; Benveniste *et al. C. R. Acad. Sci.* **289**, 1037; 1979) has elucidated the structure of PAF, largely by examining the effects of enzymic and simple chemical treatments on its chromatographic behaviours and its pharmacological actions on rabbit platelets.

As PAF was completely extracted into organic solvents, being found entirely in the chloroform phase of chloroform-methonol-water mixtures, it was known to be a lipid. However, its insolubility in chloroform alone, coupled with a low migration on silica gel thin layer chromatography (unaltered by acidification or basification of the chromatography solvent) pointed to a neutral, very polar lipid. Possible candidates at this stage were therefore glycosylacylglycerides, neutral phosphoglycerides and neutral sphingolipids, but the lipids with known hormone-like actions (steroids and prostaglandins) could be excluded. Glycosylacylglycerides and glycosphingolipids were eliminated because PAF was unaffected by sodium nitrite, which cleaves glycosidic linkages, and by reagents for free or vicinal hydroxyl and amino groups. PAF was unlikely to be polyunsaturated because of its stability to

prolonged storage and heating in air, or to contain an α,β unsaturated ether linkage such as occurs in plasmalogens because of its relative stability to strong acid. Rapid inactivation by strong methanolic base to a chloroform-soluble derivative was evidence for at least one ester linkage, and at least one base-stable fatty group. This, together with the insensitivity of PAF to sphingomyelinase, focused attention away from sphingomyelins and onto a phosphoglyceride derivative.

Inactivation of PAF by the specific phosphoglyceride phospholipases A_2, C and D established the presence of a 2-ester linkage and a 3-phosphate esterified to a polar head group which, since PAF was unaffected by methylating agents, was choline rather than ethanolamine. PAF was not inactivated by phospholipase A_1 (specific for 1-ester linkages) which was initially interpreted as suggesting the presence of an underivatised 1-hydroxyl group, but attempts to generate PAF-like activity by treatment of a variety of phosphoglycerides with phospholipase A_1 were unsuccessful (Benveniste *et al. Nature* **269**, 170; 1977).

Hanahan's group, exploiting the possibility that removal of the esterified group from PAF by methanolic base might provide an intermediate which could be chemically reesterified with various fatty acids to regenerate PAF activity, found that the resulting long chain fatty acid derivatives were inactive. They therefore tried esterification with short chain acids, and discovered that acetylation resulted in complete recovery of PAF activity with identical chromatographic behaviour. A 1-fatty ether structure for PAF was considered, which would remain chloroform-soluble after deesterification because of the stability of the ether linkage to methanolic base. Hydrogenation of the 1-α, β-unsaturated ether linkage of plasmalogens extracted from beef heart followed by deesterification and acetylation at the 2-position generated a compound identical in biological activity and chromatographic behaviour to PAF. Its structure was confirmed by IR and GLC as 1-0-alkyl-2-acetyl-sn-glyceryl-3-phosphorylcholine with the length of the alkyl chain mainly C_{16} and C_{18}.

Benveniste's group realised that their results with phospholipase A_1 would be equally consistent with an ether linkage at the 1-position of a glycerol phosphatidylcholine, and noticed that acetic anhydride treatment increased the PAF-like activity of crude but not purified PAF preparations. This alerted them to the possible presence of an acetyl group in the molecule. Methylation, hydrogenation and acetylation of a commercial ethanolamine plasmalogen underivatised at the 2-position yielded a compound identical to PAF, and they proposed the
The chemical structure of platelet-activating factor.

same structure as Hanahan's group.

Synthetic PAF appears to be the most potent activator of platelets yet described, causing shape change, aggregation and the release reaction at concentrations between 10^{-11} M and 10^{-10} M. Interest in this novel compound must be further heightened by the discovery that antihypertensive polar renomedullary lipid (APRL), a lipid found in the kidney which lowers the blood pressure of artificially hypertensive animals, has an identical type of structure (Blank *et al. Biochem. Biophys. Res. Comm.* **90**, 1194; 1979). Synthetic APRL prepared from choline plasmalogens was an extremely potent antihypertensive agent that mimicked both the acute and the prolonged antihypertensive effects of APRL extracted from the kidney. The ubiquitous occurrence of phospholipids, together with increasing awareness of their functional importance, suggests that there may be other, hitherto unsuspected roles for PAF-like compounds. □

Life in the Precambrian

from Trevor D. Ford

THIRTY years ago the known Precambrian fossils could be counted on one's fingers. Today the number has increased to the point where a computer is needed to catalogue their names and literature references, with print-out an inch thick! Moreover they are now being used stratigraphically like Phanerozoic fossils, helping to map subdivisions of Precambrian rocks previously thought to be unfossiliferous. More importantly, they provide a record, albeit patchy, of the early history of life on earth. This was the theme of a recent symposium*.

Fossils in rocks of Precambrian age fall broadly into four categories: microscopic unicellular algae (nannofossils); clusters or associations of algal cells; stromatolitic structures in limestones (generally believed to have been constructed by algae); and metazoans (of coelenterate, arthropod or 'worm' affinities). There is great controversy about their assignment to one

Noel J. Cusack is in the Department of Pharmacology, Kings College, London.

*The Symposium on 'Life in the Precambrian' was held by the Palaeontological Association in Leicester from April 10-12th 1980.

or other of the traditional Phyla, about whether or not some are fossils at all, and about their chronological relationships.

Organic-walled nannofossils extracted from sediments are generally referred to as 'acritarchs' in view of the difficulty of assigning them to any known algal groups. With some hundred or so species distinguished by their shape, size, surface ornament, wall-thickness and presence or absence of openings they have provided G. Vidal (University of Lund, Sweden) with a tool for correlation of the late Precambrian in Sweden, Norway, USSR, and Greenland. Similar studies in parts of Canada, USA, and Western Europe have extended correlation sufficiently to give a reasonably good classification of these rocks into the later Riphean and Vendian stages of Precambrian time.

The classification of acritarchs has so far lent heavily on comparisons with present day algal cells, but when various states of decay or desiccation are examined it seems that some Precambrian 'species' are, in fact, the same organism in different states of preservation. C.J. Peat (Imperial College, London) proposed that we should scrap assignations to various groups of algae and classify the Precambrian fossils into purely morphological groups of Cryptarchs. C.J. Peat, W.L. Diver (Imperial College, London) and Z. Zhongying (Nanjin University, China) also suggested that acritarch studies provide no evidence for the presence of eurkaryote cells in the Precambrian; the various 'black dots' can be explained as the shrivelled inner walls of cells, or as desiccated cell contents. This argument was accepted but there must have been eukaryote algae around to allow the evolution of sex and thus of the Metazoa. When eukaryotes appeared on Earth is still a mystery and hypotheses about Precambrian atmospheric evolution cannot yet look for support from acritarchs!

That stromatolitic structures in Precambrian limestones can provide a coarse means of correlation of Proterozoic strata has been generally accepted for some years. However, being limited to shallow shelf seas, and even then with only the digitate columnar forms being useful for stratigraphy, their value is not as great as could be desired.

As shells and skeletons had not yet evolved, fossils of Metazoan life forms in the Precambrian are almost all trace-fossils or impressions; that is, they are the marks in or on sedimentary rocks made by the activities or presence of the organisms. Inevitably their interpretation can only be made by comparison with the marks made by living organisms to-day. The Precambrian Metazoan fossils include tracks, trails and burrows on the one hand and impressions of single organisms on the other. Sequences of strata below those con-

taining well-defined Cambrian trilobite body fossils have been found in various parts of the world with a host of trails, tracks and burrows. The order in which these first appear has given rise to speculation as to whether they could be used as stratigraphic markers, and whether they were representative of a fundamental evolutionary sequence. T.P. Crimes (University of Liverpool) and M. Brasier (University of Hull), A. Peréjon and M.A. de San José (University of Madrid) described the sequences of such fossils, mainly in Spain, and concluded that there was as yet no clear evolutionary sequence, but the trace type was closely related to the immediate sedimentary environment. Exact dating by radiometric methods is not yet available but it seems that no track-making animals were present in the seas before Vendian times (i.e. pre 670Ma ago).

The kind of animal that made the tracks and burrows remains a subject of speculation, but W. Gutmann (Senckenberg Institute, Frankfurt) demonstrated that penetration of sediment could only be done by animals with metameric fluid-filled hydrostatic skeletons (coelomates). Similar hydromechanical arguments supported the identification of other impression fossils as Cnidarians, some clearly of medusoid construction.

A variety of circular or oval impressions on bedding planes are now known from many parts of the world. Recent discoveries in Charnwood Forest, Leicestershire (T.D. Ford & H.E. Boynton, Leicester University), and in Carmarthenshire (J.C. Cope, University College of Wales, Swansea) include discs with few or many annular rings; are these really fossils or are they pseudofossils of the type caused by gas or water evasion from sediments? Though most agree that they are impressions made by 'medusoids' coming to rest, R.J.F. Jenkins (University of Adelaide) described scour pits remarkably like some 'medusoid' impressions on bedding surfaces but clearly penetrating the sediments when seen in section.

The abundant and varied fauna of impressions in the Conception Group of southeast Newfoundland is still undescribed in detail though found more than 10 years ago; Conway-Morris (Open University, U.K.) showed photographs indicating the presence of several frond-like 'pennatulid' *Charnia*-type coelenterates with disc-like holdfasts, as well as lobate and spindle-shaped organisms of unknown affinity. The strong lobate impressions could well represent sediment-filled gut-cavities of jellyfish, while the spindle-shaped impressions with their chevron-marked fringes could be compared with the Portuguese Man of War coelenterate.

The assemblage of medusoid, frond-like and colonial impressions has come to be known as the Ediacura fauna from the locality in South Australia where the fossils are abundant. These also include a few trails, a segmented animal (*Spriggina*) with

a crescentric head-shield, which could be either annelid or arthropod and *Dickinsonia*, probably a flat-worm. No such fossils are yet known in Newfoundland, and only one incomplete arthropod has been found in Charnwood Forest. Neither Newfoundland nor Charnwood has yielded convincing tracks, trails or burrows, so the strata there may be slightly older, signifying sequential appearance of coelenterates, followed by segmented annelid/arthropods living freely on the sediment surface, followed by those with the hydromechanics needed for burrowing. All this seems to have taken place in Vendian (or possibly very late Riphean) times, broadly within the time span of 700 to 600 Ma ago, followed of course by the explosive evolution of shelled animals in Cambrian times.

Two other long-standing problems of Precambrian palaeontology were aired: one was the true identification of the earliest known organisms in the 3 billion year old Fig Tree Formation of South Africa, where it was argued that the size distribution of the fossils did not fit normal biological patterns and that there must therefore be some doubt as to whether they were biogenic structures. The other problem was that of the Erniettomorpha, the host of Namibian phylloid, foliate and other petrifactions imaginatively reconstructed by Hans Pflüg as the common ancestors of the Plant and Animal Kingdoms. R.J.F. Jenkins (University of Adelaide) claimed them to be a single species of frond-like type in varying states of preservation; thus *Ernietta* may be no more than another pennatulid coelenterate.

The results of the symposium thus revise our knowledge of life in Precambrian times. The earliest known Fig Tree fossils are not yet proven to be biogenic; most of the acritarchs, ranging through the Precambrian, cannot yet be assigned to appropriate algal categories with confidence; the claims of eukaryote cellular nuclei as far back as 1400Ma are not substantiated; interpretation of the various medusoid impressions must proceed with caution; the sequential appearance of trace fossil types is more a matter of sedimentary facies than of evolutionary development; and the Namibian Erniettomorpha require much closer scrutiny.

On the positive side, it has emerged that there are plenty of Precambrian fossils if only they are looked for with appropriate techniques. New forms are being discovered in many parts of the world and stratigraphic correlation schemes are already workable, even if accurate radiometric dating is not fully supportive as yet. Every find needs close scrutiny before one can be sure that it is a fossil, and even then the placement of the organism within a biological category may raise many problems. Life in the Precambrian may be obscure, but it is not dull! ☐

Rain drop sizes and rainfall
rate measured by dual-polarization radar

M. P. M. Hall, S. M. Cherry, J. W. F. Goddard & G. R. Kennedy

Rutherford and Appleton Laboratories, Ditton Park, Slough SL3 9JX, UK

A rapidly switched dual-polarization radar technique is used for the first time to obtain two-dimensional spatial distributions of the statistical characteristics of the sizes and concentration of rain drops in rain. These have been obtained using a high-resolution 10-cm wavelength radar, and the data have been used to estimate rainfall rates within small volumes to a much greater accuracy than is available from conventional radar measurements. The technique also gives a clear distinction between ice particles and rain drops.

THIS article shows some of the potential of a new radar technique that characterizes rather than assumes the distribution of rain drop sizes within a given volume, to estimate rainfall rates with improved accuracy. Many empirical relationships have been presented to compute rainfall rate from the measured reflectivity[1], but these relationships vary widely because they are governed by the statistical distribution of drop sizes at the time of measurement. This may not be significant if averaging rainfall over large volumes or long time intervals, but the assumption of an average statistical distribution to compute rainfall rates may result in a large error for applications where data are required for a small volume (for example, the pulse volume of a high-resolution radar) and without long time averages. To overcome this, the essential characteristics of the statistical distribution at a given time and place may be determined from independent measurements of the reflectivity factors obtained using vertical and horizontal polarizations[2]. The technique relies on the fact that large falling raindrops distort to become approximately oblate spheroids, each with its axis of symmetry near vertical, and that the degree of oblateness increases with drop size[3]. Consequently, the effective radar reflectivity factor measured using horizontal polarization is greater than that measured with vertical polarization.

We report here the first measurements of the two-dimensional spatial distribution of drop size characteristics using switching between polarizations which is sufficiently rapid to be regarded as simultaneous. This technique can substantially reduce errors in radar measurements of rainfall rate in small areas. Furthermore, the technique discriminates between regions of rainfall and dry ice particles. Dual-polarization radar data are expected to be of value in research fields such as radar meteorology, hydrology, cloud physics, radio science, communications engineering and erosion by hydrometeor impact.

The dual-polarization technique

Within a certain range of rain drop sizes, the numerical distribution of rain drops may be represented by an exponential function[1]. Such a function may be characterized by two parameters, N_0 and $\bar{D}$, such that:

$$N(D) = N_0 \exp(-D/\bar{D}) \qquad (1)$$

where $N(D)$ is the number of drops per unit volume per unit interval for which D is the diameter of the spherical drop with

volume equal to the actual (distorted) drop, and $\bar{D}$ is the mean value of D. Here D and $\bar{D}$ are expressed in mm and $N(D)$ and N_0 in $mm^{-1} m^{-3}$. Because of the drop distortion, and direct measurements usually being of drop volumes rather than their diameters, D_0(mm) is normally used, the diameter of that sphere for which half the volumetric water in the distribution comes from larger drops and half from smaller drops. $D_0 = 3.67 \bar{D}$ as long as $D_0 \ll D_{max}$, the diameter of the equivolume sphere of the largest drops[4].

Theoretical relationships based on work by Seliga and Bringi[2] estimate the parameters N_0 and D_0 from the effective reflectivity factors, $Z_{H,V}$($mm^6 m^{-3}$), for horizontal and vertical polarizations and the differential reflectivity factor, Z_{DR}, which is defined as

$$Z_{DR} = 10 \log_{10}(Z_H/Z_V) \quad dB \qquad (2)$$

The effective radar reflectivity factors are defined as

$$Z_{H,V} = \frac{\lambda^4 \times 10^{18}}{\pi^5 |K|^2} \int_0^{10\,mm} \sigma_{H,V}(D) N(D) dD \qquad (3)$$

where λ(m) is the wavelength, $K = (n^2 - 1)/(n^2 + 2)$ and n is
Fig. 1 Vertical scan through raincells at 13.17 UT on 15 August 1978. *a*, Absolute reflectivity factor, Z; *b*, differential reflectivity, Z_{DR}.

the complex refractive index of water. The backscatter cross-section, $\sigma_{H,V}(m^2)$, for the oblate drops at horizontal and vertical polarizations are obtained from rigorous solutions of scattering from oblate spheroids, and hence there is no assumption of the drops being small compared with the wavelength. For drops of water at the radar wavelength of 10 cm, a reflectivity factor of $1 \, mm^6 \, m^{-3}$ corresponds to a scattering cross-section of $3 \times 10^{-12} m^2$ per m^3 of cloud. Usually Z is expressed in dB relative to $1 \, mm^6 \, m^{-3}$, that is, $10 \log_{10} Z$. Unless specifically stated, Z_H is used here by convention.

The dual-polarization radar technique has been used to provide accurate measurements of Z_{DR} without excessive averaging of $Z_{H,V}$, which are time varying[5]. As with the present results, the measurements were made using a 10-cm wavelength radar mounted on the SRC's 25-m diameter paraboloidal steerable antenna at Chilbolton, UK. Alternate radar pulses were transmitted on vertical and horizontal polarizations, and examination of the time variation of the two reflectivities sampled from a single radar range gate exhibited certain points crucial to the present measurements. First, the de-correlation time of the measured reflectivity varied between 6 and 45 ms, which was considerably longer than the 1.6 ms taken to measure a pair of reflectivity values. This established that the switching was fast enough for measurement pairs to be sampled before the spatial distribution of rain drops changed significantly. Second, the cross correlation between the two reflectivity records was high, generally about 0.985. This high correlation produced a low standard error of sampling Z_{DR}, which for the system used to collect the present data was 0.1 dB. The corresponding error in Z was 0.75 dB. These random errors result in estimated standard deviations of rainfall rate, for D_0 values of 1 and 2 mm, to be 25 and 20% respectively. Limits to the errors in the calibration of Z and Z_{DR} were estimated to be 1 dB and 0.1 dB, respectively. This would result in a worst case systematic error, for D_0 values of 1 and 2 mm, of 40 and 35% respectively. By future comparison with *in situ* measurements, it is expected that bias due to the system error will be largely eliminated.

In the present study the rainfall rate has been computed using relationships between drop diameters and their fall speeds as obtained by Best[6]. These relationships assume still air, whereas there may be considerable vertical air currents in rain cells. 'Rainfall rate' is a well established characterization of the amount of rain present, and it is used here, even above ground level, without repetition of the phrase 'with respect to a frame of reference travelling at the rate of any vertical air current'.

Fig. 3 Vertical scan through raincells at 14.56 UT on 15 August 1978. *a*, Absolute reflectivity factor, Z; *b*, differential reflectivity, Z_{DR}.

Measured spatial distributions of Z and Z_{DR}

As in the system trials, the radar was operated at a frequency of 3,076 MHz and with a peak power of 500 kW. The pulse repetition frequency was 610 Hz, with alternate pulses on vertical and horizontal polarizations. Digitization of data was in 200 steps of 0.3 dB, and averaged in 128 ranges gates over 0.2 s. The sample gate width of 0.3 μs was staggered over 2 μs in 0.5-μs steps (the radar pulse width) to obtain effective range averaging over a gate width of 300 m. Spatial averaging due to dish movements amounted to one beamwidth for vertical scans (Figs 1–4) and two beamwidths for horizontal scans (Fig. 5). All averaging was of power rather than log power. The data-processing system enabled the received power at each polarization to be processed by the same logarithmic receiver and analogue-to-digital converter.

Figure 1*a* shows an example of the measured spatial distribution of Z obtained from a vertical scan through a large rain cell. There is a prominent pillar of high reflectivity at 35 km range extending to a height of 6 km, and at ranges of about 38 and 40 km there are small cells of high reflectivity that do not extend above 2 km height. Figure 1*b* shows the spatial distribution of Z_{DR} sampled at the same time as the data in Fig. 1*a*. Where the received signal level was less than 5 dB above the receiver noise level, Z_{DR} was set to a 'no data' level (as is also the case for Figs 2–4).

Fig. 2 Vertical scan through raincells at 13.55 UT on 15 August 1978. *a*, Absolute reflectivity factor, Z; *b*, differential reflectivity, Z_{DR}.

Table 1 Expected characteristics of Z and Z_{DR} at 10-cm wavelength for various hydrometeor types

Hydrometeor type	Z	Z_{DR}	Comments
Rain	High	High	Includes large oblate drops
Drizzle, cloud or fog	Low	Low	Small spherical drops of water and/or small ice particles
Dry snow flakes	Medium-low	Medium-low	Large horizontally oriented low-density aggregates
Sleet/wet snow	High	High	Large oblate horizontall oriented particles
Wet graupel	High	Negative	Large conical vertically oriented particles
Wet hail	High	Variable	Large particles: seldom spheres
Dry hail or other high-density ice particles	Medium	Low	

One of the most obvious features of Fig. 1*a, b* is that the column of high reflectivity at 35 km range has an associated high value of Z_{DR} (>2 dB) below 2 km height, but a value of Z_{DR} of only 0.13 dB (mean, with standard error 0.27 dB) between 2 and 4.5 km height. This abrupt change in Z_{DR} has been seen in many other examples. It always occurs close to the 0 °C isotherm, and marks the transition from ice particles to water drops. Unless very large asymmetries are present in low-density ice particles (snow), they will always exhibit a low value of Z_{DR} because of the low refractive index of ice and air mixtures[1]. Compact (high-density) ice particles with near-spherical shapes will intrinsically result in low values of Z_{DR}, whereas such particles with irregular shapes are likely to tumble randomly and so also have low Z_{DR}. In the absence of dual-polarization measurements, it would not be known whether the vertical column of high reflectivity in Fig. 1 were

Fig. 5 Distribution of data samples of Z, R, N_0 and D_0 in volume of rain scanned on 15 August 1978 between 13.21 and 13.26 UT—Marshall–Palmer distribution, $N_0 = 8,000 \, mm^{-1} m^{-3}$.

Subsequently, as the melting continues, the diameters would decrease (causing the observed decrease in Z), but an ice core could maintain a more oblate drop (and higher Z_{DR}) than would be possible with liquid water of the same volume. With further melting, the drop would become less oblate and the Z_{DR} would decrease. Finally, as the melting was completed, the drops would accelerate to their terminal velocity and the concentration of drops would decrease, as would the value of Z.

We shall not speculate further on the distribution of hydrometeors shown in Figs 1 and 2, but from data examined to the time of writing, the expected characteristics for various hydrometeor types are as set out in Table 1.

Fig. 4 Spatial distribution of the parameters $D_0 \, (mm)(a)$; $N_0 (mm^{-1} m^{-3})(b)$; $R (mm \, h^{-1})(c)$ computed from the data shown in Fig. 3, for heights below 1.5 km.

due to ice or water and a convective column containing rain might be assumed. When such convective columns have been observed with the dual-polarization radar, they were clearly distinguishable as having high values of both Z and Z_{DR} throughout their height.

Figure 2 shows data recorded 38 min after that of Fig. 1. There is a 'bright-band' region (of high reflectivity) at 2 km height. The cell at 33 km range has zero Z_{DR} above the bright band, whereas the cell at 22.5 km range, which has much stronger rain below the bright band, has a Z_{DR} of 0.5 dB above the bright band. It is assumed that the depression of the melting region at the centre of these cells, and that seen at 35 km range in Fig. 1, is due to the presence of compact ice particles which take longer to melt and fall faster than snow flakes. When these particles melt they scarcely change in size or fall speed, though the change to water gives the increased Z and Z_{DR} seen in Figs 1 and 2. Indeed this process probably extends to the two smaller and less intense cells to be seen between 37 and 42 km in Fig. 1. It would account for the absence of a height zone of particularly high reflectivity (bright band) near these cells.

In the range 25–30 km in Fig. 2, the largest values of Z_{DR} occur about 200 m below the bright-band height. This may be due to the following series of changes as snow flakes falling below the 0 °C isotherm melt slowly. First, water forming on the outer surface of the snow flakes would produce large effective drop diameters and the observed high Z region.

Rainfall rate and median drop sizes

Figure 3*a, b* shows data similar to those of Figs 1 and 2, but collected considerably later and in a quite different direction. There is considerable non-uniformity in the spatial distribution of Z and Z_{DR}. Figure 4*a, b, c* shows the corresponding spatial distribution of D_0 and N_0 of equation (1), and of the rainfall rate, $R (mm \, h^{-1})$, computed from Z and Z_{DR}. These are shown only for heights less than 1.5 km as we assume that the hydrometeors were water drops rather than ice particles in this region. Clearly D_0, N_0 and R all change rapidly with position. This variability may relate to many fields of study. In particular, the attenuation of radio waves due to rainfall may also be computed using N_0 and D_0 (ref. 4), and the variability of this is a current topic of study for both terrestrial and Earth-to-satellite radio paths.

Figure 5 shows values of R computed from Z_H and Z_{DR} plotted against Z (here the mean values of Z_H and Z_V), and superimposed on contours of N_0 and D_0 values. Data were collected up to a height of 1 km and up to 45 km in range whilst the radar was scanning over a width of 15°. Data for which the received signal level was within 15 dB of the receiver noise level, and samples thought to be from ground echoes, have been excluded from Fig. 5. For the lower values of Z in Fig. 5, the computed N_0 varies over the range 10^2–$3 \times 10^6 \, mm^{-1} m^{-3}$, and so some data elements have values of N_0 differing by a factor of 300 from that of the much-used distribution of Marshall and Palmer[7], for which $N_0 = 8,000 \, mm^{-1} m^{-3}$. The corresponding values of rainfall rates differ from this model by a factor of up to six. For the higher values of Z, there is apparently a much smaller spread of values of N_0, nearly all of which show lower values than that of Marshall–Palmer. However, all these samples having high Z are due to one concentrated volume of rain, and examination of data similar to those in Fig. 5, but from different rain cells, shows a quite different distribution for high Z values, with N_0 generally greater than the Marshall–Palmer value. Figure 5 also shows experimental sampling error contours at the 1 s.d.

level for D_0 of 1 and 2 mm. Evidently the data show large real differences in drop size characteristics. They also suggest that use of data from a conventional (single-polarization) radar, with an assumed drop-size distribution, may lead to large errors in computation of localized volumes of high rainfall rate.

The work described here formed part of the research programme of the Rutherford and Appleton Laboratories of the SRC.

An extraterrestrial event at the Cretaceous–Tertiary boundary

J. Smit

Geological Institute, Nieuwe Prinsengracht 130, Amsterdam, Holland

J. Hertogen

Fysico-chemical Geology, St Michielstraat 16, Leuven, Belgium

Closely spaced samples from an uninterrupted calcareous pelagic sequence across the Cretaceous–Tertiary boundary reveal that the extinction of planktonic Foraminifera and nannofossils was abrupt without any previous warning in the sedimentary record, and that the moment of extinction was coupled with anomalous trace element enrichments, especially of iridium and osmium. The rarity of these two elements in the crust of the Earth indicates that an extraterrestrial source, such as the impact of a large meteorite may have provided the required amounts of iridium and osmium.

THE Cretaceous–Tertiary boundary seems to be the only major boundary in the stratigraphic record which does not become diffuse when studied in detail[1,2]. On the contrary, all over the world the boundary can essentially be referred to one single bedding plane, even in the most complete marine sections (Gubbio, Italian Appennines[3]; Zumaya, Northern Spain[4,5]; El Kef, Northern Tunisia[6]; and many DSDP holes[7,8]). Planktonic Foraminifera occur abundantly in these sections and thus provide one of the best available ways of following the extinctions at the end of the Cretaceous[1]. This extinction and subsequent resurrection has been studied in detail in the unusually complete and thick calcareous pelagic section of Caravaca in South-east Spain[9]. Here, the topmost Maastrichtian and lowermost Palaeocene biozones (the *Micula prinsii* Zone, P. Nielsen, personal communication and the '*Globigerina' eugubina* Zone respectively) have been demonstrated. A 10-cm thick 'intermediate' bed also occurs between these zones characterized by a threefold increase of clay minerals and a peculiar indigenous fauna (J.S. in preparation). Information from the other sections mentioned above, although less complete, is compatible (Fig. 1). In the >100-m thick youngest Maastrichtian marls of the Caravaca section the rich, tropical association of planktonic Foraminifera and nannofossils[9,10] shows no significant changes up to the very last centimetre; here almost the entire association disappears within 0–5 mm. At a Maastrichtian sedimentation rate of 7 ± 3 cm kyr^{-1} (Fig. 1) this implies that the extinction took place within ~ 200 yr (ref. 1).

The impoverished association in the subsequent 10 cm intermediate bed is dominated by benthonic Foraminifera and relicts of the Cretaceous planktonic fauna, like *Hedbergella monmouthensis* (Olsson), *Globigerinelloides aspera* (Ehrenberg), *G. messinae* (Brönnimann) and *Guembelitria cretacea* (Cushman). The amazingly sharp limits of this level are apparently preserved owing to a temporarily decreased rate of burrowing, because all other sediments in the section are strongly bioturbated.

At the top of this intermediate bed the new Tertiary planktonic fauna suddenly appears in great numbers. Accompanied by the sole survivor of the terminal Cretaceous 'holocaust', *Guembelitria cretacea*, this new fauna diversifies, and shows a rapid succession of different dominant species in the lowermost 50 cm of the Palaeocene, representing the entire '*G'. eugubina* Zone[1] (Fig. 1). Hereafter the facies becomes similar to that of the Upper Cretaceous, exhibiting the same, normal, slow evolutionary changes in fauna and flora.

Analyses

To obtain more information about the extinction event (to sort out some of the current extinction models[2]), trace elements have been analysed by instrumental neutron activation (NAA) on 100 bulk samples closely spaced around the boundary: 17 elements were detected throughout the section and 10 more

93–97 pairs in correlation.

were detected in the intermediate bed only. Furthermore, we analysed five samples for iridium, osmium, selenium and nickel by radiochemical means, encouraged by a recent report of Alvarez *et al.*[12] on anomalously high levels of iridium at the boundary in the previously mentioned Gubbio section (Fig. 2, Table 1). The γ-ray countings show that the $^{184}Os/^{190}Os$ isotopic ratio in sample III (Fig. 2) is indistinguishable, within experimental error (0.1%), from the isotopic ratio in common terrestrial osmium.

Just like the planktonic fauna, none of these trace elements shows any positive or negative trend or an enrichment when approaching the extinction level. Most elements correlate nicely with the insoluble residue content (Table 2) and show a similar rise in the intermediate bed (Fig. 2). In the basal few centimetres of this bed, however, immediately above the extinction level, iridium, osmium and arsenic occur in highly anomalous quantities (450, 250 and 110 times normal, respectively) and to a lesser extent Cr, Co, Ni, Se and Sb (9, 30, 44, 40 and 20 times normal, respectively). As, Co, Ni, Cr, Se and Sb may be derived

from terrestrial source rocks. However, as Alvarez pointed out, it would be very difficult to accept a similar origin for iridium and osmium, as these elements are greatly depleted in the crust of the Earth, estimated at 0.05–0.1 parts per 10^9(p.p.b.)[11], in comparison with the average of the Solar System.

From these observations we find: (1) the extinction event was extremely abrupt, without previous warning signal whatsoever; and (2) the anomalously high amounts of iridium and osmium are clearly linked with the event.

Discussion

All the complete sections mentioned above contain almost exclusively Foraminifera and nannofossils, so any pronouncement on the syn- or diachronism of extinction with other groups or organisms remains somewhat speculative.

Attempts to achieve this correlation by palaeomagnetic means are widely debated[13–16], but irrefutable evidence for a diachronous extinction has never been produced[1]. Russell[2] has recently reviewed the current extinction models. He concluded

Fig. 1 The Cretaceous–Tertiary boundary interval in the Barranco del Gredero, Caravaca, South-east Spain. A, Micula prinsii Zone; B, 'intermediate' bed; C, *Globigerina eugubina* Zone; D, *Globigerina pseudobulloides* Zone.

that none of the existing models is entirely satisfactory, but that only a very short event, which a great part of the biosphere could not tolerate, may explain the known facts. The above mentioned points support this view.

Current extinction models may be classified in two ways; the gradual versus the catastrophic or the terrestrial as opposed to the extraterrestrial models. Most terrestrial models (nutrient depletion[17], climatic deterioration[18], rise in CCD[19], CO_2–O_2 imbalance[20], secular variations[21] and increase in volcanism[22]) are essentially gradual and should leave traces in the sediment of the imminent extinctions. None has been found yet. Reports of gradual extinction[4,19] lose their credibility on more detailed inspection[1].

There remain the catastrophic models which do not have a pre-extinction signal. One such model is the recently advocated 'Arctic flushing' of cold brackish water over the ocean surface[7,23]. In this way, however, the excess of iridium and osmium cannot be explained. Extraterrestrial influences (giant solar flare[24], supernova[2,18,25] or asteroid impact[26-28]) on the other hand are geologically speaking instantaneous and in particular the latter explains the high amounts of iridium and osmium. The frequency of disastrous impacts on the Earth or the explosion of a nearby supernova have been estimated; once every 100 Myr an impact of an asteroid or comet nucleus 10–30 km in diameter[26-28] or every 70 Myr a supernova at a distance of 50 light yr occurs[2,25]. A typical iron meteorite is $\sim 2 \times 10^4 - 4 \times 10^5$ times, and a chondrite $\sim 6 \times 10^3 - 2 \times 10^4$ times, enriched in Ir and Os relative to the crust of the Earth and when such body vaporizes on impact, or is partly broken up on entry in the atmosphere, it may deliver overdoses of Ir and Os over a large area; if we assume the Caravaca values—3 × 10⁻⁸ g cm⁻² — dispersed over the whole world and an iridium content of 5×10^{-7} g per g in a carbonaceous chondrite it may imply an impacting body of about 5 km in diameter. Geological evidence for an impact, such as a crater larger than 150 km in diameter or impact triggered sediment at the boundary have not yet been found.

The expanding shell of a supernova explosion could sweep up amounts of Ir and Os from interstellar matter.

The maximum amount that can be swept up by a supernova at 50 light yr distance is only the equivalent of the Os and Ir content of a chondrite with a diameter of 60 m. Hence it falls short by a factor of 10⁶ with respect to the required amounts (E. P. J. van den Heuvel, personal communication). Also the ratio of the stable osmium isotopes $^{184}Os/^{190}Os$ is very similar to Solar System

ratios[12]. It would be surprising if the isotopic composition in interstellar matter is within 0.1% of Solar System ratios.

Conclusions

The present evidence favours an extraterrestrial cause for the extinctions at the end of the Cretaceous. The impact of an asteroid or comet 5–15 km in diameter is the most attractive. The consequences of such an event are still poorly understood and need further investigation, as not all the facts fit this model easily.

A crucial point in the model is the near synchronous extinction of all organisms that did not cross the Cretaceous–Tertiary boundary, and the independence of the event from the known normal environmental processes going on in the latest Cretaceous.

Terrestrial catastrophe caused by cometary impact at the end of Cretaceous

Kenneth J. Hsü

Geological Institute, Swiss Federal Institute of Technology (ETH), Zurich, Switzerland

Evidence is presented indicating that the extinction, at the end of the Cretaceous, of large terrestrial animals was caused by atmospheric heating during a cometary impact and that the extinction of calcareous marine plankton was a consequence of poisoning by cyanide released by the fallen comet and of a catastrophic rise in calcite-compensation depth in the oceans after the detoxification of the cyanide.

MASS extinction at the end of Cretaceous[1] has been related to the impact of meteorites[2], asteroids[3], or comets[4,5]. The two groups of organisms most affected are large terrestrial animals and calcareous marine plankton, especially those in tropical waters. Here it is suggested that cometary impact was the major cause of the extinction of these two groups.

Catastrophic nature of the terminal Cretaceous event

High-resolution stratigraphy indicates the very short duration of the terminal Cretaceous event[6-9]. The biological changes of the marine–planktonic world across the boundary could be separated into three phases: (1) the mass extinction of a rich marine–planktonic fauna of latest Cretaceous age; (2) the pre-dominance of small foraminifera and some special nannofossils which might be surviving species from the Cretaceous[7]; (3) the appearance and evolution of robust Tertiary species.

The first phase is recorded by an iridium-rich clay or marly layer some 1 cm thick in Italy[10], and 2–5 mm thick in Spain[9]. The second phase is recorded by the *Globigerina eugubina* zone[8,9]. The third act is represented by the higher Danian microfauna and nannofossil stages. Using sedimentation rate as a basis, the duration of the terminal Cretaceous event which caused the mass extinction was estimated to be <10,000 yr (ref. 11). In fact, the span of time could be <50 yr, if the 'iridium-spike' of Spain represents the record of that event[9]. Large terrestrial animals may have become extinct at the same time as the marine plankton[12] although this is still uncertain.

Although the terminal Cretaceous event lasted a very short time, the damage was extensive[14-16] and the destruction was selective. Evolutionary changes of terrestrial plants were gradual[17] and small animals living in freshwater were virtually unaffected by the extinction[16]. However, large terrestrial animals heavier than 25 kg did not survive the catastrophe. In the marine realms, calcareous plankton was hard hit, with some groups (for example, planktonic foraminifers and nannoplankton) being virtually wiped out[14].

The extinction seemed to have hit organisms at different stages of their evolutionary development[15]. Also there seems to have been palaeogeographical selection; virtually all Cretaceous organisms which became extinct near a major peak in their evolutionary development lived predominantly in or very near to the equatorial Tethys[18], and their vacant tropical niches were eventually occupied by new Tertiary species, which had evolved from survived stocks of euritopic temperate or cosmopolitan faunas[18]. Finally, selectivity might have been an expression of resistance to environmental stress. For example, the sparse nannofloras surviving the terminal Cretaceous event were dominated by *Braarudosphaera* and *Thorascosphaera*, both of which tolerate, or even prefer, conditions adverse for the growth of other calcareous nannoplankton in the present oceans[14].

The fossil records register a catastrophic revolution of the biosphere. The almost invariable presence of a clay layer or a hardground boundary at the Cretaceous–Tertiary is evidence of a revolutionary change in the entire hydrosphere, manifested by a rise of the CCD (calcite compensation depth), which in turn, was caused by an increase of dissolved CO_2 in seawater[13,14,19].

Studies of trace elements in the clay-rich layer just above the contact indicates an unusual concentration of iridium[9,10]. The isotopic composition of Ir indicates extra-terrestrial input from a source within the Solar System[10]. Also enriched are Co, Ni, Zn, As and Sb[9].

The clay-rich layer is absent at the Cretaceous–Tertiary boundary in some deep-sea drilling holes, for example, DSDP Holes 356, 374[20,21], where biostratigraphical analyses invariably indicate, a depositional hiatus (refs 13, 21 and K. P. Nielson, personal communication). At some localities the contact is represented by a hardground[22] indicating widespread erosion or non-deposition as a consequence of bottom-current activities[21].

The climatic changes during the late Cretaceous were gradual[17,23-27]. However, isotopic analyses of deep-sea drilling cores during the past few years indicate remarkable temperature difference across the Cretaceous–Tertiary boundary[26]. An increase of 1–5 °C of both bottom and surface temperatures has been recorded by oxygen-isotope data from widely scattered localities[26-29].

Analyses of carbon isotopes of sediments across the boundary suggest a remarkable change in the chemistry of the ocean water associated with the terminal Cretaceous event. A decrease of ^{13}C of 1–3‰ has been reported[25-30] equivalent to a change produced if the whole of the terrestrial biosphere were put into the ocean[25]!

Frequency and consequences of comet collision

Impact craters are not uncommon on the surface of the Earth[31]. Based on existing craters, Hughes[32] obtained an estimate of the rate of cratering, which can be represented by

$$\phi = \frac{1}{1,400 D^2}$$

where ϕ is the rate on Earth (yr^{-1}) and D is the diameter of the crater (km). This estimates that a small crater of 200 m may be created every 350 yr, and a large crater of 100 km every 14 Myr. Based on tektite or crater ages, Napier and Clube[5] noted that large (>50 km) impact-cratering took place during the Pleistocene (1 Myr), middle Miocene (15 Myr), late Oligocene (28 Myr), early Oligocene (35 Myr), late Eocene (38 Myr), beginning of Jurassic (183 Myr), middle Triassic (210 Myr), and late Devonian (365 Myr). Considering that almost three-quarters of the Earth's surface lie under water, one can expect oceanic craters to have largely escaped detection. Nevertheless, the statistics indicate that there should have been at least one crater bigger than 500 km during the 600 Myr of the Phanerozoic.

The energy E generated by the craters has been variously

estimated[4,5,33,34] depending on the size of the object and its collision velocity. Assuming an impact speed of 24.6 km s^{-1}, Napier and Clube[5] obtained E values ranging from 0.3 to 150×10^{30} erg, associated with 80–500 km cratering which could be produced by planetesimals 4–31 km in diameter. Urey[4] used a collision velocity of 45 km s^{-1} for a comet with a mass of 10^{18} g, which is the estimated size of the Halley's comet, and found that the impact energy is 10^{31} erg, or 250×10^6 Mton. If all energy were absorbed by the atmosphere, the air temperature would rise by 190 °C. If all energy were absorbed by the oceans, the elevation of average ocean temperature would be 0.175 °C. If all the energy were used to excavate a crater, a mass of dust 3×10^{19} g could be thrown up to encircle the Earth.

Discussing Moon cratering, Gault *et al.*[35] indicated that a third of the kinetic energy is converted to heat, which is manifested in the melting and/or vaporization of both the impacting and the impacted material. However, comets falling into the ocean may heat up both the atmosphere and hydrosphere by friction. The atmospheric heating caused by a small comet may absorb the greater share of the kinetic energy. The Tungeska explosion on 30 June 1908 may have been caused by a small comet with a mass of 5×10^{10} g, and the comet may have exploded and disintegrated in the air so that numerous craters 50–200 m in diameter, instead of one large crater, were found in the impact area[2,36]. The heat was so intense that it killed all animal life within 1,000 km² (ref. 3). Aside from the kinetic energy of 5×10^{23} erg, Hughes[36] suggested that a nuclear explosion may have been triggered by neutron production as the heated comet sped through the atmosphere; he thus offered an explanation for the ¹⁴C anomaly of 1909. For a very large comet which might generate 10^{31} erg, the fraction of kinetic energy expended to heat the atmosphere depends on the entry angles and other factors. It is unlikely that the whole atmosphere could be heated to 190 °C as Urey suggested for the extreme case of total dissipation by atmospheric heating. On the other hand, the temperature produced by a speeding comet may have been so high locally that it could produce nuclear or even thermonuclear reactions (as Hughes suggested) in addition to chemical explosions. With the possible addition of chemical and nuclear energy, it is difficult to estimate the possible heating of the atmosphere. It seems, however, that a 10–20 °C increase of air temperature is possible. The heating of a large comet falling through a 5-km deep ocean can be calculated on the basis of estimating hydrodynamic resistance. Using a resistance coefficient of 0.001 typical of motions with a very large Reynolds number[37], I obtained a value of 10^{30} erg, or about 10% of the total kinetic energy for a fallen comet with 30 km diameter, 10^{18} g mass, and 45 km s^{-1} speed. These estimates suggest that the bulk of the kinetic energy would be expended after impact, causing cratering and melting of substratum, which should become an additional source of energy to raise the temperature of the ocean further.

Chemical consequences

While the physical consequences of a large cometary collision are impressive, the chemical consequences are commonly neglected because we know little about the composition of comets. There are still debates over whether comets are dirty snowballs or dust swarms[38], although the first, also known as the icy conglomerate model first formalized by Whipple, is being favoured[38–40]. The model assumes that the nucleus of comets is an icy solid body containing chemical compounds which sublimate and dissociate to provide the radicals and simple molecules that have been observed in cometary spectra[40,41]. Optical spectra showed the presence of CN, CO⁺, CH, NH, OH, and so on[42]. When Comet Kohoutek came near the Earth in 1973, hydrogen cyanide and methyl cyanide were detected 'at a reasonable abundance'[40–42]. If the concentration were 10% the amount of cyanides dissolved from a 10^{18} g of comet, and evenly distributed in ocean water would give a concentration of 0.1 p.p.m. However, the concentration would be 3 p.p.m. if the dissolved substance was concentrated in the upper 100 m only, and even more if the poison was carried by currents and thus contained within the moving surface water mass.

CO_2 and/or CO are probably also present in the nucleus of a comet. The ocean has 130×10^{18} g of dissolved carbonates[44] mainly as HCO_3^-. Deeper ocean water is undersaturated due to its higher dissolved CO_2 and lower *p*H. However, the surface seawater is supersaturated because of the high *p*H related to disturbed buffering caused by photosynthesis. The annual CO_2 extracted from the ocean by marine plankton is $\sim 0.4 \times 10^{18}$ g, which is the same order of magnitude as the probable mass of CO_2 in a 10^{18} g comet. The sudden dissolution of CO_2 from a large fallen comet can thus greatly disturb the carbonate equilibrium, so that surface waters, at least locally, may become temporarily undersaturated.

A large input of cometary carbon should also significantly alter the isotopic composition of calcareous sediments in the ocean. The isotopic composition of carbon for meteorites and for the Earth's mantle has about the same composition of −6 to −7‰ ¹³C. However, the carbonate in meteorite and the carbon in chondrite have very heavy ¹³C, with values up to more than +50‰ (ref. 45). As the CO_2 in the nucleus of a comet may have represented a distilled fraction, it should have an isotopic composition much lighter than that of the average meteorite. Assuming a cometary $\delta^{13}C$ of −25‰, a −1.5‰ carbon-excursion in dissolved carbonate can be caused by the fall of a 10^{18} g comet of which carbon atoms constitute a quarter of its mass.

Comet impact at end of Cretaceous

Probability calculations indicate that at least one large comet with a mass of 10^{18} g and impact energy of 10^{31} erg should have hit the Earth during the Phanerozoic. The nature and severity of the terminal Cretaceous catastrophe suggest that such a comet hit the Earth at that time. The comet must have fallen into the ocean so that there would be no evidence on land of a crater of this age.

The preceding analysis showed that a cometary impact may kill by three different means: large land animals could be killed by atmospheric heating, marine organisms could be killed by cyanide poisoning, calcareous marine plankton might further suffer because of a catastrophic rise of the CCD of the oceans.

If the comet fell into the ocean, the dissolution of its nucleus should have released a large quantity of HCN, CH_3CN, CO_2, and possibly also CO. The dissolved constituents should ascend with the warm water mass heated by the fallen comet, and should find their way into a surface current system and remain relatively concentrated there. Cyanide is a powerful inhibitor, arresting cellular respiration by inactivating metallo-enzymes in the respiratory process[46]. As this process is fundamental to all living organisms, cyanide dissolved in sufficient concentration could kill all kinds of marine organisms, including nannoplankton. The cyanides could be reduced through oxidation into CO_2 (ref. 46). This CO_2 added to the extraterrestrial CO_2 brought in by the comet would increase the dissolving power of seawater. The mass-mortality of phytoplanktons would further upset the CO_2 budget with a consequent catastrophic rise of CCD, leading to a virtual extinction of the calcareous planktonic life. Furthermore, phytoplankton formed the basis of the food chain for higher organisms, so that their mass mortality should cause starvation of those marine organisms[19] that had escaped cyanide poisoning. Detoxification of cyanide also produced nitrates. Experiments with living nannoplankton indicated that they would not secrete calcareous skeletons in nitrate-rich waters (B. Funnell, personal communication). Such nannoplankton would leave no fossil record, but may have evolved into the Tertiary forms which did secrete skeletons when conditions returned to the normal.

Surface currents would converge eventually into the Equatorial Current, where the greatest contamination would occur. Consequently, the catastrophe would hit hardest those organisms which inhabited the tropics. Some organisms living in the gyres of the middle latitude would escape extinction, not

only because they were more tolerant of stress conditions, but also because the gyres were regions bypassed by polluted surface currents. Note, for example, that the nannoplankton *Braarud-osphaera* is not only a tolerant species, but its modern representatives also have a population in the gyre of the Sargasso Sea[47]. Large parts of the deep-sea bottom may also have been spared lethal contamination, so that deep marine benthic communities mostly survived the catastrophe.

On land, the large vertebrates would perish under an almost instantaneous thermal stress [2,16,24], but small or aquatic animals would largely survive. Laubenfels[2] suggested that turtles may have escaped the heat wave by diving under water for hours while holding their breath, and that crocodiles preserved their species because they had buried their eggs in mud. Because the comet fell in the oceans, temperature anywhere on land may not have been sufficiently high to cause global forest fires. In any case, land vegetations could have escaped extinction as new seeds could sprout even after a pyric catastrophe.

The palaeo-oceanography after the comet fell must have been extraordinary. The increase of dissolved CO_2, the mass extinction of phytoplanktons, and the consequent pH changes may have raised the CCD to a level near or within the photic zone. Consequently, the sediment underlying the oldest fossiliferous Tertiary beds is commonly a clay or clay-rich. The input of trace elements from the fallen comet would have contributed to the unusual concentration of Ir, As, Ni and Co in this clay-lamina[9,10]. Meanwhile, the presence of molten rock material in an impact crater under the ocean should generate thermal stress and promote active bottom-circulation in the deep sea. Consequently, a depositional hiatus other than dissolution-unconformity has been noted at many deep-sea drilling sites across the Cretaceous-Tertiary boundary. The input of converted kinetic energy, possibly supplemented by the chemical and nuclear energies, would cause the rise in ocean temperature, as manifested by the $\delta^{18}O$ shift in the oldest Tertiary sediments. The input of light extraterrestrial carbon would contribute to the accompanying carbon shift.

The climatic implication of the postulated cratering is not clear. Urey[4] as well as Napier and Clube[5] estimated that the ejectas excavated by a large fallen comet may equal, or even exceed, the mass of the comet, and much of the fine dust might reach the stratosphere to block out solar radiation, thus causing glaciation. Indeed, the timing of drastic cooling near the end of Eocene and in middle Miocene[48] coincided remarkably with that of the Popigai cratering (100 km diameter) in USSR at 38 Myr and the cratering which produced the Moldavites at 15 Myr (ref. 5). The end of the Cretaceous has been considered the beginning of a general cooling on the Earth[17]. Isotopic shift did show cooling during the first few million years of the Palaeocene following the 'heating spike' (ref. 27). However, the temperature was apparently lowered to that prevailing before the catastrophe. The emerging deep-sea record indicates that the first Tertiary cooling responsible for the initiation of Antarctic glaciation came much later, at the end of Eocene[48], or the time of Popigai cratering. The different climatic effects of cratering may be accounted for by the postulate that the terminal Cretaceous comet fell into the ocean: much of the dust-sized ejectas were trapped by the ocean and did not reach the stratosphere, in contrast with the continental landing of a comet at the end of Eocene.

Conclusions

We may never find the crater, because much of the Mesozoic ocean floor has disappeared by subduction during the past 65 Myr. However, if the crater has not yet been subducted, systematic searches should locate such a large feature. The crater should have a diameter of a few hundred kilometres. Furthermore, the cratering should have created an ejecta plume, namely rock-lava steam mixture rising vertically above the crater like a volcanic eruption[49]. Collapsing under its own potential, the mixture should have developed into a *nuée ardente* or base-surge [50,51]. The mass flow at high speed should have eroded the ocean floor and formed channels. All those geomorphic and depositional features can be detected by seismic profiling.

The cratering should have produced earthquake waves and tsunami waves which would cause subaqueous slumping and turbidite deposition. We could search for the crater through a systematic recording of the size and distribution-density of such mass-flow deposits. Likewise, we could study the palaeotemperature distribution to trace the geographical origin of the anomaly. We could study the hiatus-distribution to trace the source of the stress that induced the bottom circulations. We could refine our study of geographical patterns of mass extinction. A careful examination of the existing geological records may tell us whether the crater is still to be found or if it ever existed.

Bulk attenuation in the Earth and viscosity of the core

Don L. Anderson

Seismological Laboratory, California Institute of Technology, Pasadena, California 91125

Recent studies indicate that bulk absorption is required somewhere in the Earth to explain the damping of the radial modes of free oscillation. This excess absorption, if attributed to bulk viscosity in the core, requires a value of ~500 P. This is theoretically reasonable and may be due to structural or concentration fluctuations. The shear viscosity is at least several orders of magnitude smaller.

ALTHOUGH most of the seismic attenuation in the Earth can be attributed to losses in shear[1] the damping of the radial modes suggest that bulk losses occur somewhere in the mantle or core [2-4]. If all losses were in shear value the Q value of the fundamental radial mode, $_0S_0$, would be >7,000. Several recently determined values are ~4,100. The other radial modes and compressional spheroidal overtones also have high Q values but they are more sensitive to shear attenuation than $_0S_0$, the most nearly pure compressional mode. Discussions of bulk, or volume, attenuation, therefore, must rely mainly on this mode.

The mode $_0S_0$ has only been observed infrequently and the reported values for Q have a wide variation[5]. Narrow band filtering experiments indicate that its amplitude does not die off uniformly with time after an earthquake (H. Kanamori and A. Dziewonski, personal communications). During the first few days there seems to be interference[4] with adjacent, stronger excited modes, such as $_0S_5$. The decay after about 2 weeks is less rapid than the initial decay. This could be a problem of the lower signal-to-noise ratio in the later portions of the record or a re-excitation by long-period aftershocks. Some recent results are given in Table 1. Note that relatively high values are obtained if the early part or the late parts of the record are included. The first four entries in the table are consistent, within the assigned errors, and give an average value of 4,590 with an uncertainty of ~11%. This includes two multiple station analyses. An analysis by Kanamori (personal communication) for the period 1–25 days after the Indonesian event gives a Q of 5,425. The first 2 weeks of data, however, fall in the above range. For present purposes we assume that Q of $_0S_0$ is ≤4,800 and investigate the implication. If later studies establish a higher value, then the viscosities inferred in this article will be upper limits.

Sailor and Dziewonski[4] attempted to fit the radial modes by inserting a low Q_K region in the upper mantle. The radial mode $_0S_0$, however, has little energy in the upper mantle and is most sensitive to properties of the lower mantle and outer core. Anderson and Hart[3] satisfied the $_0S_0$ data by assuming a Q_K of 10^6 in the outer core; their models also have a low Q_K, 426–847, in the inner core. These values were based on body wave and inner core shear mode data, as well as on the radial modes.

The problem is not unique as there is little resolving power in the available compressional or high-Q modes. We have found that a uniform Q_K of ~10^4 throughout the Earth also satisfies these data. If only the core contributes then a slightly smaller value for this region is implied. Body wave studies[6,7] of the outer core give values for Q_P ranging from 10^2 to 10^4. This suggests that the core may contribute significantly to the observed attenuation. Furthermore, bulk attenuation is well documented in fluids and, in particular, in liquid metals. Because of the dominance of shear losses in the mantle it will be difficult to determine the bulk contribution, if any, of this region. In this article we estimate the bulk viscosity of the core from the

damping of the radial modes and then investigate if this is a reasonable number for liquid iron at core conditions.

Models

We have investigated a large number of models to learn more about possible distributions of bulk attenuation in the Earth. These included constant Q_K and frequency-dependent Q_K models, all of which satisfy the shear sensitive spheroidal and toroidal mode data. The excess absorption is attributed to bulk losses in pure compression. Some of these models and the resulting radial mode Q spectra are given in Table 2. SL8 is from Anderson and Hart[3] and is a frequency-independent Q structure. The others are a result of the present study and, at low frequencies, have $Q_K \sim \omega^{-1}$ as appropriate for a relaxation mechanism. The values given are for a period of 1,000 s. The radial mode data and results for three models are shown in Fig. 1.

The value of ~7,000 for Q $(_0S_0)$ which is obtained for Earth models exhibiting only shear losses can be reduced to a value near 4,200 by introducing a Q_K of ~10^4 distributed uniformly throughout the mantle and core. If the bulk losses occur only in the core an average Q_K of ~2×10^3 in this region is required. As

$$Q_K^{-1} = (2\pi f / \rho c^2) \eta_v \qquad (1)$$

for fluids this gives an effective bulk viscosity, η_v, for the core of ~500 P; this is an average value. ρ is the density; c, the velocity of sound; and $f = \omega/2\pi$ is the frequency. Pressure is likely to increase viscosity so that smaller values may be maintained at the top of the core. There is no detailed information about the variation of Q_K with depth but we know that the attenuation of P waves is much greater in the inner core than in the outer core. This suggests that the relaxation time in the inner core is closer to seismic periods than is the case in the outer core, and that the relaxation time increases with depth. This implies an increase in viscosity with depth. Note that previous investigators have proposed that the inner core is a highly viscous fluid rather than a crystalline solid[8].

Table 1 Q of $_0S_0$

6,687	13	2	0–25	Indonesia	5
Longer times included					
5,527	2	7	2–45	Indonesia	*

* A. Dziewonski (personal communication).

Physics of attenuation in fluids

We will first consider sources of attenuation in the outer core. The absorption of sound in a liquid at low frequencies is given by

$$\alpha/f^2 = (2\pi^2/\rho c^3)\{\tfrac{4}{3}\eta_s + (c^2\beta^2\theta T/C_p^2) + \eta_v\}$$

where α is the spatial attenuation coefficient, β the thermal expansion coefficient, θ the thermal conductivity, C_p the specific heat, η_s the shear viscosity, η_v the volume viscosity, and T the absolute temperature. The first two terms on the right-hand side represent the classical Stokes–Kirchoff absorption due to shear stresses and thermal conductivity. The first term is important in the attenuation of longitudinal waves in liquid metals, but is absent for strains involving pure compression. The second term is important at laboratory frequencies but is negligible at core conditions and seismic frequencies. The remaining term is called the excess absorption and is due to bulk or volume viscosity. Both η_s and η_v contribute to damping of longitudinal waves in fluids but only η_v would contribute to the purely compressional strains which dominate the fundamental radial mode. In liquid metals at low pressure η_v is similar in magnitude to η_s (ref. 9).

Several mechanisms contribute to bulk viscosity in simple fluids. One is structural relaxation due to perturbations in the short-range order caused by the sound wave. Another is due to concentration fluctuations in alloy systems. These are comparable in magnitude in laboratory conditions but have quite different temperature, and possibly pressure dependencies. The dominant mechanism may, therefore, be different at core conditions from that in laboratory conditions. A high bulk viscosity at conditions prevailing in the core is not necessarily inconsistent with a much lower shear viscosity. The characteristic times for shear and structural relaxation are likely to be similar as they are both controlled by short range diffusion. The relaxation time due to concentration fluctuations or chemical reactions may be quite different.

Longitudinal waves in liquid metals typically are within an order of magnitude of

$$Q = 10^{11}/f$$

which in normal conditions is composed of three roughly equal parts due to shear viscosity, thermal conductivity and bulk viscosity, or excess sound absorption[9]. The attenuation in liquid metals in laboratory conditions would be quite negligible at seismic frequencies. However, the effects of pressure and alloying lengthen the characteristic relaxation times.

Bulk viscosity of molten iron

The bulk viscosity of a pure liquid metal is due to structural rearrangement as there are no internal degrees of freedom. Two-state theories have been developed to explain structural relaxation associated with pressure changes. The assumption is that a liquid is a mixture of two structural states with differing mole volumes and energies.

We use the two-state theory of Herzfeld and Litovitz[10] and Flinn et al.[9] to estimate the structural volume viscosity of iron just above the melting point, T_m, and its relation to the shear viscosity;

$$\eta_v = \frac{x_1 x_2 V}{RT_m}\left(\frac{\Delta V}{V} - \frac{\beta \Delta H}{C_p}\right)^2 \tau K^2$$

and

$$\eta_v/\eta_s = \frac{(2n-12)(12-n)}{n^2}\left(\frac{VK}{RT_m}\right)^2\left(\frac{\Delta V}{V} - \frac{\beta \Delta H}{C_p}\right)^2$$

$$x_2 = (12-n)/n = 1 - x_1$$

where x_1 and x_2 are the mole fractions of the two states which differ by ΔV and ΔH in molar volume and enthalpy, and n is the coordination number. For liquid iron at low pressure we take $n = 9$; $V = 8\ \mathrm{cm^3\ mol^{-1}}$; $\Delta V/V = 0.1$; $\Delta H/RT_m = 3$; the bulk modulus, $K = 1.3\ \mathrm{Mbar}$ (10% less than solid iron); $\beta = 70 \times 10^{-6}\ \mathrm{K^{-1}}$, $C_p = 10.2\ \mathrm{cal\ mol\ K}$; and the relaxation time, $\tau =$

5×10^{-12} s. This relaxation time is typical of liquid metals[9] (the other values are from refs 9, 11, 12, 13). $\Delta V/V$ is calculated from Fürth's relation. These parameters give

$$\eta_v = 3\ \mathrm{cP}$$

and

$$\eta_s = (5/3)\eta_v = 5\ \mathrm{cP}$$

for molten iron at low pressure. The measured value for η_s is 4.8–7.0 cP (ref. 14) and the near equality of η_s and η_v is consistent with measurements on other liquid metals[9]. Thus, the two-state theory gives satisfactory results at low pressure which leaves us to investigate the properties at core conditions.

The main effect of pressure and temperature is on the bulk modulus K and the relaxation time τ. The bulk modulus of the core is 4–10 times larger than iron at normal conditions[11,15] and relaxation times have been estimated to be of the order of 10^{-8}–10^{-9} s (ref. 16). Therefore, bulk viscosities of 4–6 orders of magnitude larger than at low pressures, or η_v of 10^2–10^4 P, are expected. The associated shear viscosities would be in the range of 10–100 P. The neglect of the effect of temperature and pressure on the other parameters would decrease these estimates slightly but probably by less than an order of magnitude. This estimate of η_s satisfies the lower limit (10 P) of Bukowinski and Knopoff[16] and the upper limit for the top of the outer core of 10^6 P based on the lack of damping of the 18.6-yr principal nutation[17].

Effect of alloying

Based on density and cosmic abundances, the core is likely to contain up to 10% Ni and other siderophiles and a similar amount of light element such as O or S. There are additional volume relaxation mechanisms associated with alloys and solutions. In particular the relaxation times can be much longer than those due to shear and structural relaxations. This might be significant in explaining the apparent frequency dependence of Q of P waves in the outer core[6,7]. There is a suggestion of a linear increase of Q_P with frequency which, if verified, indicates that the seismic band is on the high frequency side of the absorption band in the outer core. As this cannot be true for shear waves unless the unrelaxed shear modulus of the core is much lower than the rigidity of the inner core we may need a low-frequency volume relaxation mechanism. This contribution to the bulk attenuation and volume viscosity depends on concentration and may eventually shed light on the nature of alloying elements in the core.

Flinn et al.[21] found a highly temperature-dependent absorption mechanism operating in binary melts which is not present in the pure metals.
Fig. 1 Q values for the radial modes, $_nS_0$. The models SL8 and 1219 have moderate bulk attenuation in the core. Model QBS has high bulk attenuation in the upper mantle. The data are from ref. 2 and Table 1.

The extra absorption in liquid metal alloys is probably due to concentration fluctuations. Theoretically it is inversely proportional to the diffusivity or directly proportional to the shear viscosity. As with the structural viscosity it is also proportional to the square of the bulk modulus and can therefore, be expected to increase with pressure. More importantly it is a function of the curvature of the Gibbs potential versus concentration relation and, therefore, becomes very large in the vicinity of a critical point. Unfortunately, it is not possible to estimate the relaxation time of this mechanism in the core.

We conclude that structural and concentration fluctuations may be responsible for bulk viscosity in the core and contribute to the excess absorption of the radial modes.

Relaxation theory of bulk attenuation

The Q due to bulk losses in a relaxing solid or viscoelastic fluid is

$$Q_K^{-1}(\omega) = (\Delta K/K)\omega\tau_v/(1 + \omega^2\tau_v^2) \qquad (2)$$

where $\Delta K/K$ is the modulus defect and τ_v is the volume relaxation time.

$\Delta K/K$ is the fractional difference between the high frequency and low frequency moduli. This has not been measured for liquid metals but is typically ~ 0.3 for other liquids. The decrease in bulk modulus on melting of metals ranges from ~ 5 to 30%. This may be of the same order as the modulus defect for molten metals. The bulk moduli of glasses are often taken as approximately the same as the high frequency moduli of fluids. This gives a modulus defect of 0.2–0.7 for most liquid–glass systems. These estimates give Q_{min} between 10 and ~ 3 at $\omega\tau = 1$. The increase in bulk modulus at the inner core–outer core boundary is about 5% (ref. 15). If this is taken as $\Delta K/K$ we obtain an estimate of 40 for the minimum Q_K of the core at $\omega\tau = 1$. A Q_K of 2×10^3 at a period of 20 min (the period of $_0S_0$) implies, from equation (2) that $\tau \sim 4$ s or 10^4 s. The smaller value would be consistent with the solid-like behaviour of the inner core for short-period body waves. The location of the inner core–outer core boundary would then be frequency dependent and the inner core would apparently be smaller at free oscillation periods. Such a frequency dependence has, in fact, been suggested by Gutenberg[8]. A frequency-dependent inner core boundary could explain the discrepancy between free oscillation and body wave determinations of the properties of the inner core. For example, the shear velocity obtained from PKJKP[18] is ~ 20% smaller than that obtained from the free oscillation data[15,19] for a fixed inner core radius. These results can equally well be interpreted in terms of a 20% decrease in inner core radius in going from body wave to free oscillation periods. Glass-like transitions, or transitions from fluid-like to solid-like behaviour typically take place over a small range of temperature. The sharpness of the inner core boundary could be explained by such a transition occurring over a small range of pressure.

Interpreting the data in this way requires that the seismic data

Table 2 Effect of bulk dissipation (Q_K) in mantle and core on Q of radial modes

* Ref. 3. Q_K (inner core) = 426–847.
† Q_K of outer core varies with depth.

for the outer core be on the low frequency side of the relaxation peak. For the outer core

$$Q_K^{-1} = \frac{\Delta K}{K}(\omega\tau_v) \qquad (3)$$

and, for the inner core

$$Q_K^{-1} = (\Delta K/K)/\omega\tau_v \qquad (4)$$

The boundary of the inner core, then, corresponds to $\omega\tau = 1$ and this is where attenuation would be a maximum. For a 1-s body wave the inferred relaxation time at the inner core–outer core boundary is $(2\pi f)^{-1}$ or ~ 0.2 s. This is close to the value deduced from Q_K in the outer core.

Bulk attenuation in solids

There are also several mechanisms that can contribute to bulk modulus or volume attenuation in solids. These include thermoelastic, magnetoelastic and phase changes. Because of the wavelength of seismic waves, thermoelastic losses would be due to heat flow between adjacent grains rather than from the compressional part to the dilatational part of the wave. Composites of anisotropic grains or grains of different compressibility should exhibit intergranular thermoelasticity[20]. This depends on grain size, d, and thermal diffusivity, D. This mechanism gives a modulus defect and relaxation time of

$$\Delta M/M = \gamma\beta TR$$

$$\tau = d^2/3/\pi^2 D$$

where R is a measure of the grain anisotropy and varies between 0 and 1.

For $\beta = 10^{-5}\,K^{-1}$, $\gamma = 1$, $T = 2,000\,K$, $d = 1\,cm$ and $D = 0.001\,cm^2\,s^{-1}$, values appropriate for the mantle,

$$\Delta M/M = 0.02R$$

or

$$Q_{min} = 100/R$$

and

$$\tau = 3\,s$$

The thermal diffusivity of iron at core conditions is $\sim 0.06\,cm^2\,s^{-1}$ (ref. 21) which shifts the characteristic thermal relaxation time to about 0.5 s for the inner core. Therefore, the intergranular thermoelastic mechanism will contribute most at body wave frequencies and for $R = 0.1$ gives a Q_K at ~ 1 s of the order of 10^3. At a period of 20 min the Q_K associated with this mechanism will be $\sim 10^6$. A distribution of grain sizes will spread out the band and reduce the peak absorption.

For grain sizes of 1 cm or smaller the intergranular thermoelastic mechanism is small at free oscillation periods. Its presence, however, makes our estimate of Q_K in the core a lower bound. The low Q_P of the inner core at body wave frequencies may be due to this mechanism or due to the proximity to the relaxation peak in a viscoelastic fluid, as discussed earlier.

Conclusion

The damping of the radial modes can be satisfied by invoking a bulk dissipation in the core equivalent to Q_K (core) of 2×10^3. This implies a bulk viscosity of 500 P. A two-state theory for bulk viscosity of liquid iron gives satisfactory results at low pressure and predicts a value at core pressures which is consistent with the radial mode data. The main uncertainty in the theoretical result is in the relaxation time. The same theory predicts a shear viscosity in the core which is several orders of magnitude lower. A relaxation theory of bulk viscosity suggests a relaxation time of the order of 1 s in the core. The same result is obtained if we assume that the inner core has relaxation times greater than body wave periods so that it seems to be a viscous fluid exhibiting unrelaxed moduli. Current estimates of the shear relaxation time in the core are highly uncertain, but are $\ll 1$ s. As structural relaxation times are expected to be the same

as shear relaxation times this may suggest that a lower frequen[c]y mechanism, such as concentration fluctuations in an alloy, is responsible for the bulk viscosity.

If appreciable bulk attenuation occurs in the mantle and inner core, for example, by intergranular thermal currents, then th[e] estimate of Q_K^{-1} in the outer core will be reduced and the estimate of the bulk viscosity will be an upper bound. The thermal relaxation time is not a strong function of temperature or pressure. It would, therefore, be a coincidence if it happened to be near the period of $_0S_0$. The viscous relaxation times, on the other hand, are strong functions of the external variables and it is not unreasonable that they sweep through the seismic band in the core.

Isolation of the chicken thymidine kinase gene by plasmid rescue

Manuel Perucho*, Douglas Hanahan*, Leah Lipsich† & Michael Wigler*

* Cold Spring Harbor Laboratory, Cold Spring Harbor, New York 11724
† Department of Biochemistry and Molecular Biology, Harvard University, Cambridge, Massachusetts 02138

We have used the bacterial plasmid pBR322 as a vehicle to isolate genes coding for selectable markers from higher eukaryotes. In this way, we have obtained the chicken thymidine kinase (tk) gene as a 2.2-kilobase EcoRI/HindIII insert in pBR322. The cloned gene transforms tk⁻ animal cells with an efficiency equal to that of the cloned herpes simplex virus-1 tk gene.

SEVERAL genes of higher eukaryotes which encode major products of at least one tissue have been isolated, chiefly by using specific hybridization probes to screen genomic DNA fragments cloned into prokaryotic vectors[1-3]. Recently, an efficient method has been developed for the stable genetic transformation of cultured animal cells[4-7]. Genomic DNA from wild-type cells has been used as donor to transfer genes coding for selectable markers, such as thymidine kinase, adenine phosphoribosyl transferase and hypoxanthine phosphoribosyl transferase, to mutant recipient cells[8-11]. These developments make possible the isolation of genes coding for selectable markers. We describe here the isolation of a chicken thymidine kinase (tk) gene by means of 'plasmid rescue'. The chicken tk gene was chosen because an excellent recipient for DNA-mediated gene transfer was available in Ltk⁻, a tk-deficient mouse cell line, which has never been known to revert spontaneously to the tk⁺ phenotype[8-12]. In addition, this gene has the advantage that both the tk⁺ and the tk⁻ phenotypes can be selected[13].

Experimental design

In our scheme, chicken DNA is first digested with a restriction endonuclease which does not cleave tk and then ligated to similarly digested *Escherichia coli* plasmid pBR322 coding for ampicillin resistance (amp)[14]. This concatenated DNA is used to transform mouse Ltk⁻ cells to tk⁺. Some transformants can be expected to contain the chicken tk gene linked to pBR322 sequences. Next, the pBR322 sequences residing in the transformant are used to 'rescue' the flanking animal host sequences containing the tk gene. For this, DNA from the transformant is cleaved with a second restriction endonuclease, ligated in cyclization conditions and then used to transform *E. coli* to ampicillin resistance. Plasmid clones resulting from transformation of *E. coli* are then tested for the ability to transfer tk back into tk⁻ animal cells. This scheme is illustrated in Fig. 1, in which the restriction endonuclease HindIII is used for the first set of cleavage/ligations and EcoRI is used for plasmid rescue.

Transformation of Ltk⁻ cells

Restriction endonuclease-cleaved chicken DNA was tested for the ability to [transf]er tk to Ltk⁻ recipients to identify the enzymes that d[o no]t cu[t th]e chicken tk gene. Among these were HindIII, BamHI and EcoRI. HindIII was chosen for initial constructions. HindIII-cleaved chicken DNA was ligated to HindIII-cleaved pBR322 at 1:1 mass ratios, and then used to transform Ltk⁻ cells by the calcium phosphate co-precipitation method[9,15]. We found that pBR322 sequences inhibited transformation in amounts exceeding 2 μg per 10^6 cells. Therefore, 1 μg of chicken DNA which was ligated to 1 μg of pBR322 was co-precipitated in calcium phosphate along with 18 μg of Ltk⁻ DNA. This mixture was added to each plate containing 10^6 cells. Cells were then selected in hypoxanthine/aminopterin/thymidine medium as reported before[7]. After 2 weeks, 12 tk⁺ colonies were cloned and cultured for further analysis.

All tk⁺ transformants were examined for the presence of pBR322 sequences by blot analysis[16,17] using ^{32}P-labelled nick-translated[18,19] plasmid as probe. Although 8 of 12 transformants contained 2–20 copies of pBR322, we could not assume that any of these was adjacent to the tk gene because far more pBR322 sequences than tk genes were present during transformation, and co-transformation with unlinked DNA fragments does occur[17].

To establish the relationship between pBR322 sequences and the chicken tk gene, a second round of transformation and
Fig. 1 A schematic illustration of the isolation of the chicken thymidine kinase gene (tk) by plasmid rescue. H, R and B refer to restriction endonuclease sites for *Hind*III, *Eco*RI and *Bam*HI, respectively (see text for details).

selection was necessary. Total DNA from each of four primary transformants containing pBR322 sequences was used to create eight secondary tk⁺ transformants. Blot analysis showed that 4 of the resulting 32 transformants (derived from 3 primary transformants) contained a single pBR322 sequence. Such sequences were not present in vast excess in the genomic DNA of primary transformants and so we concluded that the pBR322 sequences present in the secondary transformants were adjacent to the tk gene.

Rescue of pBR322 sequences

To rescue pBR322 sequences from transformed animal cells, these sequences must contain plasmid replication functions and an antibiotic resistance gene. Rtll-1a, a secondary transformant derived from the primary transformant tll, contained a *Hind*III fragment which annealed with nick-translated pBR322 and co-migrated with *Hind*III-cleaved pBR322. We concluded that no loss of pBR322 sequences occurred during transformation of this cell line. *Eco*RI and *Bam*HI were each used to rescue pBR322 from this line because they do not cleave the chicken tk gene and each cleaves pBR322 only once, on either side of the single *Hind*III site of the circular pBR322 molecule[20].

DNA from Rtll-1a was digested, ligated in cyclization conditions, and used to transform *E. coli* χ1776 (ref. 21) by a high efficiency procedure (D.H., in preparation). The efficiency of transformation of χ1776 with this cellular DNA was about 100-fold lower than expected from reconstruction experiments. Two ampicillin-resistant colonies were obtained which contained pBR322 derivatives: a 9.2-kilobase plasmid, pR-1, derived from *Eco*RI cleavage, and an 8.5-kilobase plasmid, pB-1, derived from *Bam*HI cleavage. Restriction maps of these plasmids are presented in Fig. 2.

We next verified (by hybridization) that the rescued plasmids were derived from the transformed mouse cells. Rescued

quences were nick translated and used as probes in blot analysis of restriction endonuclease-cleaved Rtll-1a DNA. Figure 3a and b show that *Bam*HI-cleaved pB-1 co-migrated with an homologous *Bam*HI fragment of Rtll-1a. Furthermore, Fig. 3c and d show that *Hind*III/*Bam*HI-cleaved pB-1 co-migrated with homologous fragments in *Hind*III/*Bam*HI-cleaved Rtll-1a. Double digestion with *Hind*III and *Bam*HI yielded two fragments not resolved in these conditions. Similarly, Fig. 4a-d show that *Eco*RI-cleaved pR-1 co-migrated with an homologous *Eco*RI fragment of Rtll-1a and that *Eco*RI/*Hind*III cleavage products of pR-1 each co-migrated with homologous fragments present in *Eco*RI/*Hind*III-cleaved Rtll-1a. The 0.6-kilobase *Hind*III/*Hind*III fragment is not visible.

We conclude that both pR-1 and pB-1 were rescued from animal cells into *E. coli*. From their respective restriction maps, a restriction map was reconstructed of pBR322 and its flanking host sequences in Rtll-1a (Fig. 2). This map was verified independently by blot analysis after cleavage of Rtll-1a DNA with a variety of restriction endonucleases.
Fig. 2 Restriction maps and derivations of rescued plasmids. DNA from the secondary transformant Rtll-1a was prepared as previously described[17] and cleaved with either *Eco*RI or *Bam*HI. Digested DNA was then cyclized with T4 DNA ligase at a DNA concentration of 5 μg ml⁻¹. Cyclized DNA was used to transform *E. coli* χ1776 by a procedure to be described elsewhere (D.H., in preparation). Two plasmids, pR-1 and pB-1, were obtained from *Eco*RI-cleaved and *Bam*HI-cleaved, cyclized DNA, respectively. Restriction maps of these plasmids are shown, with pBR322 sequences denoted "▬" and inserted sequences denoted "〰". The numbers refer to kilobase pairs. From the maps of the two rescuants, a restriction map was reconstructed of the sequences flanking the pBR322 sequence resident in Rtll-1a (top line). pR-1 was found to encode tk and was renamed pchtk-1. pchtk-1 was cleaved with *Hind*III and cyclized to construct pchtk-2, which contains only the 2.2-kilobase *Eco*RI/*Hind*III insert encoding tk. Below is a restriction map (to scale) of the 2.2-kilobase insert. At the bottom is a restriction map (to scale) of the 12.5-kilobase insert of λchtk-1 isolated from a Charon 4A chicken library[22]. *Pvu*II, *Sma*I and *Sac*I sites are not mapped on the phage. Restriction enzymes are *Bam*HI (B), *Eco*RI (R), *Hind*III (H), *Kpn*I (K), *Sma*I (Sm), *Sac*I (Sc), *Xba*I (X), *Pvu*II (P) and *Bgl*II (Bg). Restriction enzyme digestions and ligations carried out in conditions described by the vendors (Bethesda Research Labs and New England Biolabs).

The 3.5-kilobase BamHI fragment of HSV-1 strain F (ref. 7) containing the HSV-1 tk gene was cloned into the BamHI site of pBR322. The orientation of the tk fragment is the same as the pFG5 clone of Colbere-Garapin et al.[25].

The sequences flanking pBR322 in the secondary transformant Rtll-1a could theoretically have arisen from chicken or mouse (or both), depending on events occurring during transformation. Blot analysis showed that the sequences contained in both pR- and pB-1 were derived entirely from chicken. The HindIII/BamHI insert of pB-1 co-migrated with an homologous HindIII/BamHI fragment of chicken DNA (Fig. 3c, e) whereas pB-1 showed no homology to mouse DNA in stringent hybridization conditions (Fig. 3f–j). Similarly, HindIII/EcoRI digestion of pR-1 generated one fragment of 4.3 kilobases containing only pBR322 sequences and three fragments of 2.2, 2.0 and 0.6 kilobases. These latter three fragments co-migrated with homologous fragments in chicken DNA cleaved with HindIII and EcoRI (Fig. 4c, e). Moreover, pR-1 showed no homology to mouse DNA (Fig. 4j).
Fig. 3 Blot analysis of the pB-1 rescuant. pB-1 was ^{32}P labelled to high specific activity (2×10^8 c.p.m. per µg) by nick translation[19] and used as probe in Southern blots[17] to DNA electrophoresed in 1.0% agarose gels: a, BamHI-cleaved pB-1 (40 pg with 2 µg salmon DNA carrier); b, BamHI-cleaved Rtll-1a (10 µg); BamHI- and HindIII-cleaved DNA from: c, pB-1 (40 pg, with carrier); d, Rtll-1a (10 µg); e, chicken (10 µg); f, i, various secondary, chicken tk⁺ mouse transformants (primary transformant tll used as donor) (10 µg each); j, Ltk⁻ (10 µg). Arrows on the left are sizes (in kilobases) of restriction fragments of adenovirus-2. Digestions were in 30 µl final volume, 2 units of enzyme per µg DNA for 3 h at 37 °C.

pR-1 contains the chicken tk gene

pR-1 and pB-1 were tested in transformation assays for ability to transfer tk activity to Ltk⁻ cells. Although pB-1 gave no tk⁺ colonies, treatment of mouse cells with pR-1 yielded approximately 10 tk⁺ colonies per ng, only slightly below the frequency observed with a pBR322 clone containing the 3.5-kilobase BamHI fragment of HSV-1 which encodes the herpes simplex virus tk gene (pTK-2) (Table 1). These observations strongly suggested that pR-1 encoded the chicken tk gene, and this was confirmed by hybridization studies. As expected, pB-1 showed no homology to chicken tk⁺ mouse transformants (Fig. 3). On the other hand, pR-1 showed homology to chicken tk⁺ mouse lines but not to Ltk⁻ itself (Fig. 4f–j). Moreover, mouse cells transformed with pR-1 contained these chicken DNA sequences (Fig. 5b, c, d). No transformants contained HSV-1 tk sequences. Further confirmation was obtained by comparing the physical properties of the tk activity expressed in transformants with that of chicken, mouse and herpes tk. Isoelectric focusing of cytoplasmic extracts showed that transformants obtained using pR-1 as gene donor expressed a tk activity with the same isoelectric point (9.7) as that of 6-day-old chick embryo extracts and distinguishable from mouse (9.0) and herpes $(6.1)^{22}$. We therefore conclude that pR-1 encoded the chicken tk gene. pR-1 was renamed pchtk-1.
Fig. 4 Blot analysis of the pR-1 (pchtk-1) rescuant. pR-1 was used as probe in blots to DNA electrophoresed in 1.0% agarose gels: a, EcoRI-cleaved pR-1 (40 pg with 2 µg salmon carrier); b, EcoRI-cleaved Rtll-1a DNA (10 µg); EcoRI- and HindIII-cleaved DNA from: c, pR-1 (40 pg with carrier); d, Rtll-1a (10 µg); e, chicken (10 µg); f, g, h, various secondary chicken tk⁺ mouse transformants (primary transformant tll used as donor) (10 µg); i, a chicken tk⁺ primary transformant (10 µg); j, Ltk⁻ (10 µg). Arrows indicate sizes (in kilobases) of restriction fragments of adenovirus-2. Digestions were as in Fig. 3.

Localizing the chicken tk gene

pchtk-1 contains three chicken fragments bounded by EcoRI and/or HindIII sites: a 2.2-kilobase HindIII/EcoRI fragment, a 2.0-kilobase HindIII/HindIII fragment and a 0.6-kilobase HindIII/HindIII fragment. From its construction, we expected that the three chicken specific fragments of pchtk-1 were not contiguous in the chicken genome (Fig. 1). Thus, any of these fragments could have encoded the chicken tk gene. Blot analysis using nick-translated pchtk-1 as a probe showed that DNA from chicken and chicken tk⁺ mouse transformants contained in common only a 3.0-kilobase HindIII fragment. Thus, the 2.2-kilobase EcoRI/HindIII fragment contained the active gene. To test this rigorously, a second plasmid, pchtk-2, was derived from pchtk-1 by cleaving it with HindIII, cyclizing it and using it to transform E. coli. The resultant plasmid contained only the 2.2-kilobase HindIII/EcoRI fragment inserted into pBR322. This plasmid transformed Ltk⁻ to the tk⁺ phenotype with an

a b c d e f g h
Fig. 5 Presence of the 1.4-kilobase *Eco*RI/*Pvu*II fragment in transformants, chicken, plasmid and phage DNA. DNAs from various sources were digested with *Eco*RI/*Pvu*II, electrophoresed in 1.5% agarose gels, transferred to nitrocellulose filters and hybridized *in situ* with ^{32}P-labelled, nick-translated, *Kpn*I/*Xba*I fragment of chicken tk (2×10^8 c.p.m. per µg). *a*, Charon 4A clone, λchtk-1 (200 pg); *b–d*, three different tk$^+$ mouse transformants obtained using pchtk-1 as gene donor (8 µg each); *e*, chicken (8 µg); *f*, pchtk-2 (50 pg with 2 µg salmon DNA carrier); *g*, HSV-1 tk$^+$ mouse transformant (8 µg); *h*, Ltk$^-$ (8 µg).

efficiency approximately equal to that of pchtk-1 (Table 1).

To localize the tk gene in more detail, we identified restriction sites on the 2.2-kilobase *Hin*dIII/*Eco*RI fragment using enzymes that cleave the fragment once (Fig. 2). pchtk-2 was cleaved to completion with each enzyme and the linearized plasmid was used in transformation assays (Table 1). By this procedure, we localized one end of the tk gene to the fragment bounded by the *Eco*RI and *Kpn*I sites, and the other end to the fragment bounded by the *Xba*I and *Pvu*II sites. Thus, a functional chicken tk gene is no larger than 1.4 kilobases and may be as small as 1.0 kilobase.

The plasmid carrying the biologically active chicken tk gene has had a complex history: it was passaged through mouse cells as well as through *E. coli*. To verify the structure of the tk gene independently, we have cloned it by an alternative and more familiar route. A library of chicken DNA[23,24] distributed into the bacteriophage λ vector, Charon 4A, was screened using nick-translated pchtk-2 as probe. DNA from one cloned phage (λchtk-1) contained a 12.5-kilobase chicken insert which transferred tk efficiently to Ltk$^-$ cells (Table 1). Restriction mapping and blot analysis (Figs 2, 5) confirmed the colinearity of the tk genes cloned in phage and by plasmid rescue.

The scheme we have demonstrated for the isolation of the chicken tk gene represents the first instance of the purification of a higher eukaryotic gene using essentially genetic techniques. In principle, this method is applicable to any higher eukaryotic gene coding for a selectable marker. We emphasize, however, that the isolation of tk has been greatly facilitated by its small size, a strong selection system and an excellent recipient cell used to detect its transfer.

Cash *et al.*[1] reported the possible detection of an extreme ultraviolet (EUV) source in the constellation Pavo. They suggested HD192273 as a possible candidate and cited a TD-1 satellite observation indicating that this star is also unexpectedly bright at 1,565 Å. Wegner[2] reported visual photometric and spectroscopic data for HD192273 and concluded that it is apparently a normal B-type star. Shipman and Wegner[3] have reviewed the available data on HD192273 and suggested that all of the observations could be explained if this object were an analogue of HZ22, an evolved, mass-exchange, binary. We report here a recent observation with the UV spectrometer (UVS) aboard the Voyager 1 spacecraft. An upper limit (2σ) of 8×10^{-3} photon cm^{-2} s^{-1} Å^{-1} is placed on the 534–776 Å flux from HD192273 at the time of observation. This is ~10% of the 500–780 Å flux reported from Pavo by Cash *et al.* The 1,565 Å flux observed by TD-1 is confirmed and is consistent with the stellar parameters determined by Wegner. Discounting the possibility that HD192273 is an EUV variable, it is probably not the potential source reported by Cash *et al.*

The Voyager 1 UVS is an objective grating instrument covering 534–1,701 Å with 126 contiguous photon counting pixels having maximum sensitivity shortward of 1,000 Å (refs 4, 5). Pre-flight laboratory calibrations were based on calibrated channeltron detectors, traceable to NBS standard photodiodes, and indicate a transfer error of ±15% from the photodiodes. The in-flight EUV sensitivity has been demonstrated in several
Fig. 1 The shaded area shows the portion of the sky mapped in this observation. The $0.1 \times 0.86°$ UVS field of view is shown in three positions corresponding to the spatial bins from which the stellar signal (S) and the background spectra (B) were taken. The ellipse shows the position of the 100% response contour of Cash *et al.* when a possible detection of an EUV source was made. Further mapping of this area by the Voyager UVS is planned.

ways: the Voyager 1 UVS has observed the integrated solar disk. Comparison with the published solar spectrum[6] confirms the EUV sensitivity calibration. UVS measurements of Io's ion torus[7] (534–1,000 Å) are consistent with the optical observations at other wavelengths, *in situ* measurements, and theoretical models of the torus. The recorded strength of He I 584 Å scattered by the interstellar medium confirms the EUV sensitivity of the UVS during the observation reported here.

The UVS was pointed towards HD192273 between 01.14 UT on 27 November 1979 and 21.13 UT on 28 November 1979. Spacecraft attitude control motions caused the field of view to wander over a portion of the sky shown in Fig. 1. Using pointing information, the spectra were accumulated into spatial bins. The bin (S in Fig. 1) having the strongest signal in the 912–1,701 Å range corresponds in position to HD192273. No other source was detected within the shaded area. A background spectrum was accumulated from the two areas B on Fig. 1. This background spectrum (total integration time 2,496s) was appropriately subtracted from the stellar spectrum (total integration time 2,880s) to correct for the He I 584 Å and H Lyα emission scattered by the interstellar medium plus any cosmic UV radiation.

No statistically significant signal was found in the 534–776 Å range. The measured count rate corresponds to a flux of $(2 \pm 3) \times 10^{-3}$ photon cm^{-2} s^{-1} Å^{-1} over the wavelength range. The stated 1σ uncertainty includes counting statistics and the background subtraction. The upper limit (2σ) on the EUV flux is 8×10^{-3} photon cm^{-2} s^{-1} Å^{-1} or about 10% of the flux reported by Cash *et al.* from Pavo. Of course, not all the area included in their field has been mapped in this observation, and it is possible that a source exists outside the area over which the observations over-lap. Nor can we exclude the possibility that the EUV source is variable. However, it is unlikely that HD192273 varies by more than a factor of 10 in the EUV as it is not known to vary in the visible or UV. The UVS observed a 1,396–1,701 Å flux of 1.4 ± 0.3 photon cm^{-2} s^{-1} Å^{-1} in fair agreement with the flux of 1.7 photon cm^{-2} s^{-1} Å^{-1} observed by TD-1 in the 1,400–1,730 Å band[8].

The latter (1,565 Å) flux is too bright for the Henry Draper type of B8 but not for an earlier spectral type. Wegner determined $T_e = 27,000$ K and log $g = 4.8$ from his visual observations. Using the model atmosphere results of Kurucz[9] for these parameters, the theoretical ratio of the flux in the 1,565 Å band to the flux in the V band was estimated to be ~30. The absolute calibration of α LYR (ref. 10) provides a relation between apparent magnitude and flux. The observed[3] $V = 8.83$ for HD192273 and the magnitude–flux relation imply a predicted flux of 1.2 photon cm^{-2} s^{-1} Å^{-1} at 1,565 Å which is in reasonable agreement with both the observed Voyager 1 and TD-1 fluxes.

We conclude that HD192273 is probably not the 'potential' EUV source reported by Cash *et al.* and that it is not abnormally bright at 1,565 Å for its effective temperature and gravity. However, the problem of understanding its apparently large distance from the galactic plane in terms of its small radial velocity and short life expectancy remains.

Note added in proof: Additional UVS observations of the Pavo region were obtained in February 1980. Observations of HD192273 on 6 and 18 February are consistent with the upper limit on EUV flux given above. A search of 95% of the field of Cash *et al.*[1] showed no evidence of an EUV source; a 2σ upper limit of 3.2×10^{-2} photon cm^{-2} s^{-1} Å^{-1} can be placed on any source within the area. In addition, no FUV (911 – 1,200 Å) sources other than HD192273 were found within the search area, down to a sensitivity threshold of 0.08 the brightness of HD192273. It is unlikely that HD192273 is an EUV variable, as no EUV flux has been detected in three separate observations.

Spectra of SO₂ frost for application to emission observations of Io

L. S. Slobodkin, I. F. Buyakov & N. S. Triput

Luikov Heat and Mass Transfer Institute, Byelorussian Academy of Sciences, Minsk, 22078, USSR

R. D. Cess, J. Caldwell & T. Owen

Laboratory for Planetary Atmospheres Research, State University of New York, Stony Brook, New York 11794

We have obtained, and describe here, laboratory reflection spectra of SO₂ frost from 6 to 14 μm. For rapid deposition of the frost layer at a deposition temperature of 80 K, the frost exhibits a strong absorption band at 7.5 μm, consistent with the possible Voyager 1 identification of such a band due to suspended solid SO₂ particles within Io's atmosphere. This compatibility does not, however, exist if the frost layer is formed at 140 K or if the layer is formed slowly. Thus it may be possible to obtain information concerning the particle formation process using more detailed laboratory SO₂ frost spectra.

Although spectra of the Galilean satellites Europa, Ganymede and Callisto clearly indicate water ice absorption features representing free water in the form of surface frost[1], no water ice features have been identified in reflection spectra of Io. Instead, it has been suggested[2,3] that observed Io absorption bands in the near IR represent solid SO₂. The presence of solid SO₂ on Io's surface is compatible with the recent Voyager 1 IR experiment[4], from which gaseous SO₂ was identified on Io, with an estimated abundance consistent with a gaseous SO₂ atmosphere which is in equilibrium with solid SO₂ at the local surface temperature. As Pearl *et al.*[4] have point out, an obvious source of gaseous SO₂ consists of volcanic plumes with possible precipitation of solid

SO_2 particles from the plumes. This hypothesis would be compatible with the suggestive identification of solid SO_2 within Io's atmosphere from Voyager I emission observations over a warm region containing a volcanic feature[4]. This tentative identification refers to a possible weak absorption between 1,320 and 1,340 cm^{-1} (7.5 μm). Existing laboratory transmission spectra[5–8], for formation temperatures ranging from 20 to 93 K place the ν_3 band of solid SO_2 in this region.

But the spectra of condensed phases depends on several factors. For example, Slobodkin, et al.[9] have shown that the spectral locations of solid NH_3 bands can depend on deposition rate and deposition temperature. Moreover, they emphasize that solid particles, comprising either a cloud or a haze, are formed rapidly, and that laboratory frost-layer simulation should attempt to mimic such a rapid formation process. The point is that the polycrystalline structure of the solid is influenced by formation rate. In view of the considerable current interest concerning the composition of Io's surface and atmosphere, we have obtained new IR SO_2 frost spectra for a limited range of deposition rates and deposition temperatures. Reflection spectra have been obtained from 6 to 14 μm for 3-mm thick frost layers which were formed at 80 K, subsequently warmed to 140 K, and then cooled back to 80 K. Because, for a given formation rate, there is no distinction between warming a frost layer to a given temperature or forming it at that temperature[9], the 140 K spectra would be representative of a 140 K formation temperature. Two deposition rates were used; slow deposition at 7.5 μm min^{-1} and rapid deposition at 1,500 μm min^{-1}.

The slow deposition spectra are shown in Fig. 1. The rather minor changes in the spectra on warming from 80 to 140 K could be indicative of a polycrystalline phase transition. The 80 K (cooled from 140 K) spectrum is quite similar to the 140 K spectrum, as would be expected, as phase transitions do not occur on cooling. The 8.9-μm feature in this spectrum seems to be a blend of the 8.8-μm band and a weaker 9-μm feature, both of which appear in the other two spectra, rather than a shift in the location of the 8.8-μm band. The spectra in Fig. 1 do not agree with the transmission spectra for 20–93 K formation[5–8]. In these studies the ν_1 and ν_3 bands are located at 8.7 and 7.5 μm, respectively. Our spectra indicate a slightly shifted ν_1 band, and there are considerable differences in the 7–8 μm region. But this seems to be due to formation rate differences.

Our rapid deposition spectra are shown in Fig. 2. For 80 K formation the 7.5 and 8.7 μm band locations coincide precisely with the 20–93 K transmission spectra[5–8]. This suggests that the polycrystalline phase which was produced in obtaining the
Fig. 2 Solid SO_2 reflection spectra for a frost layer formed by rapid deposition (1,500 μm min^{-1}).

transmission spectra actually coincides with our rapid-deposition frost layers. The 9.8-μm band, which appears clearly in all our spectra, is not mentioned in any of the transmission studies. But as pointed out by Herr and Pimentel[10], reflection spectra, in contrast with transmission spectra, tend to enhance weak absorption features, and thus the possibility exists that the 9.8-μm band was simply not evident within transmission spectra. Indeed Smythe et al.[2], in their near-IR reflection study, have identified several solid SO_2 bands which apparently were not evident in the most detailed of the transmission spectra[7]. The weak band at 6.2 μm, as well as the broad feature at ~11.8 μm, are most likely due to contaminant water which is also present in the near-IR reflection spectra of Smythe et al.[2], and Fanale et al.[3].

As previously discussed, we anticipate the rapid deposition frost layer to be representative of solid SO_2 particles formed within Io's atmosphere, and this is consistent with the possible identification of a solid SO_2 absorption feature at 7.5 μm from the Voyager I emission observations[4]. But this would only be compatable with the 80 K formation spectrum of Fig. 2. Evidently, at least for rapid deposition, there is a significant alteration in the structure of our frost layer on warming from 80 to 140 K, with the 140 K spectrum showing no feature which could be attributed to the possible Voyager I identification. This structural change could be partially due to changes in grain size on warming the layer, but grain-size changes should not induce a shift in band locations[11]. Instead, at least for rapid deposition, a significant polycrystalline phase transition is probably the primary cause of the alteration in our rapid-deposition spectra on warming from 80 to 140 K. The consistency of our rapid-deposition 80 K spectrum with the 93 K transmission spectra[5,6] would in turn imply that the phase transition occurs between 93 and 140 K. This further suggests that if the observed Voyager I absorption feature is due to solid SO_2 particles within Io's atmosphere, then the particles are formed at a temperature below 140 K.

If the above hypothesis is correct, it would be useful for diagnostic purposes to have laboratory spectra available covering a broad range of wavelengths and formation temperatures. We plan to obtain such spectra.

A fluid-dynamical model of differentiation and layering in magma chambers

J. Stewart Turner

Research School of Earth Sciences, The Australian National University, Box 4, Canberra 2600, Australia

Large igneous intrusions characteristically have a systematic gradation in mineral composition from top to bottom, often associated with a horizontally layered structure on several scales[1,2]. Current theories[3] invoke the settling of denser crystals as the mechanism responsible for separating the various components from the solidifying melt. However, recent laboratory experiments[4,5], using crystallization from aqueous solutions to model the essential fluid-dynamical processes, have documented another significant way in which chemical differentiation of the liquid can be caused by relative motion between crystals and the remaining melt. The growth of crystals of a denser component on a side-wall boundary leaves behind less dense fluid. (This corresponds to the behaviour of many common magmas, notably those of the calc-alkaline series. However, in tholeiitic basalt magmas, of the type which commonly form layered intrusions, crystallization leads to an increase in density of the remaining melt.) The lighter fluid rises to the top of the chamber in a boundary layer flow, which builds up a stable density gradient, by the 'filling box' mechanism[6,7] previously discussed in other contexts. In the latest experiments reported here, the process of differentiation is demonstrated explicitly: starting with a homogeneous mixture of two solutes in water, crystallization at a vertical boundary produces overall vertical composition gradients, as well as density stratification accompanied by smaller scale layering.

Previous, more extensive experiments[4] have systematically examined the additional effects due to crystallization in a 'double-diffusive' system[8] (that is, one in which the difference in molecular diffusivities of the several components has an important role). Sodium carbonate solution was chosen as the working fluid, because of its high solubility and large change in solubility with temperature, and various initial density distributions and cooling configurations were explored. Potassium carbonate has been used as the second solute in both the previous and the present experiments. The geometry adopted for the new experiments was suggested by the observations[9] of basaltic pillars on the sea floor, which are cooled by water circulating through a hollow conduit along their centres, but this analogy is immaterial for the present purpose and will not be pursued further here. The results are believed to have a more general significance, and depend only on the occurrence of crystallization at any side boundary.

There has been much recent discussion[10] about the non-newtonian behaviour of natural magmas. A finite yield strength
Fig. 1 The density profile produced in Na_2CO_3 solution, by the upflow accompanying crystallization at a central rod, 47.5 h after cooling began. The initial homogeneous density distribution is also shown. (The refractive index of small samples withdrawn from the tank was the property actually measured, with a calibration to relate this to density.)

can certainly inhibit the settling of small crystals, but such effects should be less important in the present case. First, crystallization at a boundary will leave the adjacent melt relatively free of crystals in suspension, so removing one likely cause of a non-newtonian viscosity. Second, a boundary layer of less dense fluid with increasing total buoyancy will eventually begin to flow upwards, whatever the nature of the viscosity. Our experiments using aqueous solutions should thus reproduce the important overall features of the prototype flows.

The experimental tank was made of Perspex, 40 cm × 20 cm in cross-section and 30 cm deep. It was fitted with a 9-mm o.d. copper tube, projecting vertically through a seal in the centre of the base and extending the whole depth of the tank. All the runs described below were started by filling the tank to a depth of ~25 cm with a homogeneous solution (or mixture of solutions), covering it with a floating, insulating lid, and then cooling it from the centre by circulating liquid coolant through the central tube from a bath held at known temperature.

Consider first an experiment using a single solute, Na_2CO_3 in an aqueous solution of specific gravity 1.183. When coolant, at 0 °C, was pumped through the central tube, a cold downflow was observed near the central rod. After a few minutes, however, crystallization began, with the crystals adhering to the cooled surface, and a strong upflow was seen instead. This upflow occurs because the formation of crystals of $Na_2CO_3 \cdot 10H_2O$, of specific gravity 1.44, leaves behind a boundary layer of depleted solution which is less dense. This layer, in which the change of concentration more than compensates for the density increase due to the decreased temperature, rises to the top of the chamber. The lightest (most depleted) solution is continually fed
Fig. 2 Shadowgraph of the experiment described in the caption to Fig. 1. The axisymmetric crystal mass, shown in silhouette, is surrounded by 'double-diffusive' layers, produced by cooling the stable density gradient at the centre.

Fig. 3 Shadowgraph showing the layers in the fluid, and associated scallops on the crystals, formed by cooling a homogeneous solution of Na_2CO_3. (Initial specific gravity = 1.164, coolant temperature −2.5 °C. Photograph at 44 h.)

to the top of the region, and density stratification is eventually built up (see Fig. 1).

Another striking feature of this stratification is shown in Fig. 2, taken just before the density profile was measured. The shadowgraph reveals a series of layers (of which there are also some indications in the rather coarse density profile of Fig. 1). These are a consequence of the double diffusive instabilities characteristic of top and side cooling of a stable composition gradient[8]. In the present case, the side cooling probably dominates, and the layering is equivalent to that produced near a melting iceblock; this effect has recently been studied[11,12] in the context of melting icebergs.

The upflow in the boundary layer which feeds light fluid to the top of the box results in the individual layers being pushed downwards with time. Thus the crystals do not in general remain in the same relation to the interfaces as they grow, and any persistent layer structure in the crystals tends to be obliterated. At a later stage of other experiments, however, the interfaces did stay at a fixed level, and the growth (or in some cases resolution) of the sodium carbonate crystals is then clearly affected by the existence of, and circulation in, the fluid layers (see Fig. 3). Again there are close analogies to what has been observed[12] during the melting of vertical ice walls.

The behaviour to be expected when there is more than one solute can be deduced (at least in retrospect) from what has already been presented, but this case is of such importance that it is worth studying directly. The tank was filled with a homogeneous mixed solution of specific gravity 1.358, made up of Na_2CO_3 (21.45 wt %) and K_2CO_3 (11.87 wt %). In this case, the coolant was gradually brought down to 0 °C from room temperature (20.4 °C). Crystals nucleating near the central rod at first did not remain attached, but fell out to form a conical pile at the base. As the temperature dropped to about 12 °C, the crystals attached themselves, the upflow of lighter fluid began, and the chamber stratified as described previously. It was found by later analysis of the crystals that pure $Na_2CO_3 \cdot 10H_2O$ was again crystallizing out. Thus as well as being depleted in sodium, the upward flowing boundary layer was relatively enriched in potassium. Instead of recording the density distribution, it is now more instructive to plot the Na/K ratio (Fig. 4). This demonstrates directly that 'differentiation' has been produced in the experimental tank. There is a systematic variation in composition of the solution with depth which becomes more pronounced with time.

Layering is also observed in this case, as shown in Fig. 5. Several of the interfaces can be clearly identified with steps in the concentration profiles, and in the associated density profile (which was measured, but is not reproduced here). Note also the smaller steps and sharp interfaces near the top of the tank. We suspect that these are 'diffusive' interfaces produced by the
Fig. 5 Shadowgraph of the experiment described in the caption to Fig. 4, taken just before the samples were withdrawn for the concentration profile measurement. In addition to the features seen in Fig. 2, note the fine-scale 'diffusive' layers at the top.

opposing vertical composition gradients (K_2CO_3 being relatively more concentrated at the top), rather than by the horizontal temperature gradients responsible for the formation of the deeper layers. Similar structures have been observed in earlier experiments[4].

In conclusion, we re-emphasize that the deductions made above do not depend critically on the particular geometry chosen, or on the complexity of the crystallizing system. The scaling problem has been considered elsewhere[4], and it has been shown that the much larger viscosity of liquid magmas is compensated for by the larger scale, so that the laboratory and prototype flows can be dynamically similar. We have drawn attention to a previously neglected fluid process, that of upflow in the boundary layer accompanying crystallization of a heavier component at a side boundary. This is in principle capable of setting up large scale concentration and density gradients through the depth of a magma chamber, and in combination with double-diffusive processes, it can also produce smaller scale layering. It seems at least worth comparing the consequences of this model with some of the detailed petrological and geochemical data on igneous intrusions.

I thank C. F. Chen, with whom these crystallization experiments were begun, D. L. Corrigan and R. Wylde-Browne for

Evidence from Canada and Alaska on plate tectonic evolution of the Arctic Ocean Basin

P. B. Jones*

Dome Petroleum Ltd, Box 200, Calgary, Canada T2P 2H8

A new model for the plate tectonic evolution of the Amerasian sector of the Arctic Ocean is suggested here using data from petroleum exploration on its margin. More than 500 km of late Cretaceous dextral slip is indicated for the SW–NE trending Kaltag fault system in Alaska and northwestern Canada. Terminating against the Kaltag, an older fault system trends along the Canadian Cordillera, with dextral slip of thousands of kilometres. Its offset by the Kaltag is postulated to follow the southern margin of the Canada Basin. Restoration of the offset creates a great circle lineament from the Asian end of the Lomonosov Ridge through western North America along which Jurassic–Cretaceous transform movement could have accommodated spreading about the Alpha Ridge. Accretion of the newly-formed lithosphere to a Palaeozoic Canada Basin created the Amerasian Basin in essentially its present configuration, modified by subsequent Kaltag movement.

The Arctic Ocean is divided into the Eurasian and Amerasian basins, separated by the Lomonosov Ridge. Proponents of seafloor spreading have generally agreed that the Eurasian Basin orginated through Cenozoic spreading about the Nansen (Gakkel) Ridge[1]. The origin of the Amerasian Basin, bounded by the Lomonosov Ridge and the Arctic continental margins of North America and Siberia, is more controversial[2,3]. Petroleum exploration on the continental shelf and mainland of Alaska and northern Canada provides new data on this problem. The Richardson Mountains of Northwestern Canada are part of a broad shear zone flanked on the west by the Kaltag fault system (Fig. 1), whose principal movement was during the late Cretaceous[4]. Local and regional facies changes in Lower and Upper Cretaceous sediments occur between adjacent fault blocks[5,6], suggesting an aggregate dextral slip for the entire fault and shear zone of several hundred kilometres. The youngest strata involved in faulting are of Maastrichtian and possible Palaeocene age[7]. Offshore geophysical surveys and deep drilling have delineated an Upper Cretaceous–Tertiary sedimentary basin containing >8 km of regressive clastic sediments[6,8]. The oldest sediments drilled so far are of Palaeocene age. The sediments are deformed, but the structures are synsedimentary and do not seem to be affected by the underlying belt of strike-slip faults, implying that those movements had ceased in

* Present address: ITC Ltd, 101–4th Street SW Calgary, Canada T2P 1R9.

the early Tertiary or latest Cretaceous.

The Kaltag fault system extends from western Alaska through northwestern Canada and passes northeastward beneath the Beaufort Sea[9,10]. It separates east–west trending structures of the Brooks Range from the Interior Platform and from the eastern part of the Canadian Cordillera, represented locally by the Mackenzie Mountains. From the Beaufort Sea, it is believed to follow the linear continental margin of the Canadian Arctic Archipelago[4,6,11], with minor offset by the Wegener fault, to Greenland. The trend is continued along the southern margins of the Eurasian Basin and Barents Shelf, forming a lineament 4,500 km long.

South-west of the Richardson Mountains, the Kaltag fault intersects the Tintina fault (Fig. 2). Following the trend of the Canadian Cordillera, the Tintina fault is a major strike-slip fault whose post-Palaeozoic dextral slip, based on offsets of equivalent strata, is at least 450 km[12]. It is one of several dextral strike-slip faults, sub-parallel to one another, closely associated with ophiolite zones and areas of blueschist metamorphics, trending through the Western Cordillera of North America to the America landfall of the East Pacific Rise[13,14]. Palaeolatitudes of Palaeozoic rocks west of this zone are several thousand kilometres south of palaeolatitudes of coeval strata in the North America craton and eastern part of the Cordillera[15]. Actual displacements of the Tintina and associated faults are probably much greater than the measured offsets.

The Tintina fault terminates at its northern end against the Kaltag fault. It is postulated that it was displaced 560 km northward by the Kaltag, and that the offset continuation is represented by the sourthern margin of the Canada Basin, an abyssal plain underlain by oceanic lithosphere[8,16]. Several workers have speculated on the presence of a fault bounding the Alaskan margin of the basin [11,17]. It is suggested that such a fault, herein designated the Beaufort–Laptev fault, follows the southern margin of the Amerasian Basin from the Beaufort to the Laptev Sea, at the Asian end of the Lomonosov Ridge. Although the margin is not as linear as some fault-controlled ocean margins, the irregularity may be due to modification by volcanism and sedimentation, and by the anticlockwise rotation of the sector east of long. 180° implicit in the Kaltag fault movement.

Restored to their Mesozoic continuity (Fig. 2), the Beaufort–Laptev and Tintina faults formed part of a lineament that followed a great circle from the Asian end of the Lomonosov Ridge via the Western Cordillera of North America to the landfall of the East Pacific Rise. It is suggested that this lineament was a Mesozoic transform fault zone through which Pacific seafloor spreading was transferred to spreading about the Alpha Ridge, a Mesozoic analogue of the Cenozoic fault system connecting spreading about the Nansen Ridge with opening of the North Atlantic. Major movements along this lineament ceased when the Tintina and Beaufort-Laptev sectors became separated at the end of the early Cretaceous. Subsequent Pacific seafloor spreading was perforce accommodated by subduction beneath the Aleutian Arc.

Relative to localities in North America, the apparent polar wander (APW) path shifted abruptly at the end of the Lower Cretaceous (100 Myr)[15], the time when the offset of the Tintina–Beaufort–Laptev lineament by the Kaltag fault was initiated. Although APW paths do not indicate absolute movements of the continents relative to a magnetic north pole, it is surely more than coincidence that the angular shift of the APW path is similar to the angle between the Tintina and Kaltag faults.

Spreading about the Alpha Ridge during the Jurassic and early Cretaceous created a large trapezoidal ocean basin which, through accretion to the pre-existing Canada Basin, gave rise to the Amerasian Basin in almost its present form, modified by dextral movement of its eastern margin in the late Cretaceous.

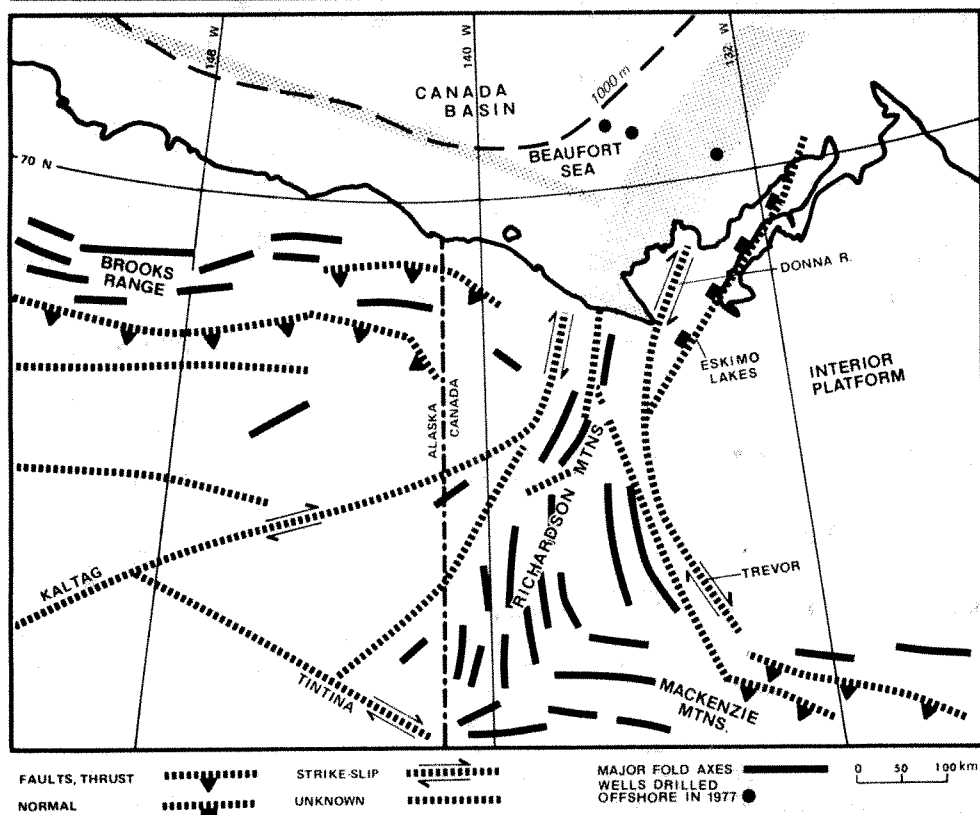
Major discontinuities of Phanerozoic sedimentary and metamorphic facies coincide with both the Kaltag and the Tintina faults[6,18]. Maps of Mississippian through Upper Cretaceous facies can be redrawn palinspastically to relate


Fig. 1 Tectonic map, northwestern Canada and Alaska. Stippled areas show seaward extension of Kaltag fault and adjacent shear zone and hypothetical offset of Tintina fault. (Modified after refs 9, 24).

Fig. 2 Model for the evolution of the Amerasian Basin and associated displacements along Tintina and Kaltag faults.

movements of these faults to the evolution of Upper Palaeozoic and Mesozoic palaeogeography of northwestern America. The restoration of Permian facies (Fig. 3) is used as an example, since it provides a new solution to the problem of provenance of Permo-Triassic sandstones of northern Alaska, reservoir rocks in the giant Prudhoe Bay oilfield. These sediments were derived from an adjacent land mass in the area now occupied by the Canada Basin[19,20], leading many workers to conclude that their source was the Canadian Arctic Archipelago, split off from Alaska by Jurassic opening of the Canada Basin[21-23]. Figure 3 shows a common sediment source for the Permian of both northern Alaska and the Canadian Cordillera. Matching of facies across the Tintina fault entailed restoration of 1,200 km of Jurassic–Early Cretaceous dextral movement, a distance that corresponds approximately with the width of oceanic lithosphere produced by seafloor spreading about the Alpha Ridge.

This study was sponsored by the Beaufort Sea Exploration Group of Dome Petroleum Ltd. D. A. Horn, N. G. Koch, and J. K. Lentin assisted with the manuscript.

Large historical earthquakes and seismic risk in Northwest Syria

J. P. Poirier, B. A. Romanowicz, & M. A. Taher

Institut de Physique du Globe, Université Paris VI, 4 place Jussieu, 75230 Paris Cedex 05, France

Arabic documents and manuscripts containing detailed descriptions of material damage and ground deformation due to earthquakes in northwestern Syria have been used to establish a catalogue of local seismicity and assign epicentral intensities to the earthquakes. Large earthquakes affecting the northern Syrian fault system apparently have a recurrence interval of about 340±60 yr. Here we use this figure and a relationship between recurrence interval and seismic moment, recently proposed by Molnar, to estimate the maximum seismic moment $(0.5 \times 10^{27} \leqslant M_0^{Max} \leqslant 3.7 \times 10^{27})$ and the magnitude $(7.1 \leqslant M_w \leqslant 7.7)$ of the largest earthquakes in northwestern Syria. Such an earthquake is not expected for at least one century but an earthquake with magnitude $6 \leqslant M_w \leqslant 7$ might occur in the near future.

The great linear fault system which begins near the Dead Sea rift and continues, north of Lebanon, by the Syrian faults has exhibited only a moderate seismicity since earthquakes have been instumentally recorded (since the turn of the century).

However, archaeological and historical documents show that major earthquakes have affected Palestine and Syria in earlier times. Many biblical events can be interpreted as great earthquakes[1] affecting the Dead Sea system. Further north, Antioch, once the capital of Syria (now Antâkya in Turkey) and one of the great cities of the Mediterranean ancient world was repeatedly destroyed by terrible earthquakes[2]. Ambraseys[3] showed, and it is now generally accepted, that the instrumental record is too short to give an unbiased image of the seismicity of a given area and that historical records must be used. Thus, for large shallow earthquakes at plate boundaries, it has been possible to define recurrence intervals for large earthquakes around the Pacific and in the Caribbean[4] and forecast that shocks should occur in the near future in areas for which the recurrence interval was nearly the length of time elapsed since the last large shock. Nur and Reches[1] have recently found a recurrence interval of 200 yr for 6–7 magnitude earthquakes on the Dead Sea system.

From Arabic manuscripts and documents, Taher[5] has gathered data on historical earthquakes in the Near Middle East from the seventh up to the eighteenth century. Clearly, many earthquakes essentially affected the region of Antioch, Aleppo, the Border zone (north of Antioch along the Turkish border) and the Orontes Valley (Hama, Homs, and so on). This region corresponds to the area north of Lebanon, threaded by the Syrian fault system which comprises the straight Masyâf fault, the Gharb and Antioch grabens and the Karasu fault (Fig. 1). There is field evidence[6] that the whole system functions as left lateral strike-slip faults, thus constituting the northern part of the transform fault bounding the Arabian plate on the west, the southern part of which forms the Dead Sea system which has been shown to be the seat of a sinistral strike-slip motion[1,7]. The northern and southern parts of the fault system are separated by the compressive Lebanon region and can be considered as different rupture zones. It is, therefore, reasonable to concentrate on the seismic activity of the Syrian fault system alone. Accordingly we catalogued local seismicity (Table 1) using data from: Greek and Roman historians[2] from AD 52 to 588; Taher[5] for the period covered by arabic texts (seventh—eighteenth century); Karnik[8] for the nineteenth century and instrumental seismicity up to 1951; the ISC Bulletin (Edinburgh) from 1951 to the present.

We considered only the meizoseismal zone in the region of Antioch, Aleppo and the Orontes Valley. Epicentral intensities I_0, on the Mercalli modified scale, have been assigned to the earthquakes by using the description of damage given in the documents.

We find essentially two classes of earthquakes: the ones with $VII \leq I_0 \leq X$ and the ones with $I_0 \geq X$ for which there is evidence of ground deformation of tectonic origin and/or particularly great damage. We did not include the shocks with $I_0 < VII$ nor those with $M_L < 5$. The spectrum of epicentral intensity I_0 versus time displays a rather regular pattern with two recurrence intervals (Fig. 2): Large earthquakes ($I_0 \geq X$) occurred in AD 115, 528, 859, 1139 and 1822 with a recurrence interval:

$$T_1 = 341 \pm 62 \, yr$$

smaller earthquakes ($VII \leq I_0 < X$) occur with a recurrence interval:

$$T_2 = 71 \pm 51 \, yr$$

Quakes with $I_0 \geq VII$ reported at dates differing by <5 yr were counted as one in the average). Although the earthquake of AD 115, under Trajan was very severe, the evidence to assign it an intensity $I_0 \geq X$ is not as good as for the others; however, if the unmistakable quasi-periodicity is to have a physical meaning, the earthquake of AD 115 should be included. A gap in the spectrum for smaller earthquakes between 1408 and 1822 is attributed not to the lack of seismicity but to the lack of chroniclers in Damascus under the Ottoman rule: only the great earthquakes felt in a wide area would have been recorded.

Molnar[9] recently estimated the average recurrence interval T

of events with seismic moments $\geq M_0$ but not greater than M_0^{max} (the seismic moment of the largest earthquakes which have occurred on the fault):

$$T = \frac{(M_0^{max})^{1-\beta} M_0^{\beta}}{(1-\beta)\dot{M}_0^{\Sigma}}$$

where $\beta \simeq \frac{2}{3}$ and where $\dot{M}_0^{\Sigma}$ is the average production rate of seismic moment given by:

$$\dot{M}_0^{\Sigma} = \mu l L \bar{V}$$

where μ is the rigidity of the crust; l, the width of the fault; L, the active length of the fault system and $\bar{V}$, the average rate of motion along the fault.

We will use Molnar's formula, not to estimate the recurrence intervals from the knowledge of the seismic moments but the other way round, for the following reasons: our historical evidence refers to local earthquakes, and all reports of damage refer to the same geographical area, hence, we can compare the quakes on the basis of the importance of the damage and of the ground deformation. We therefore assume that the earthquakes to which we have assigned the maximum epicentral intensity on this basis (and which have a recurrence interval $T_1 \simeq 341$ yr) are the ones which have the maximum seismic moment M_0^{max}.

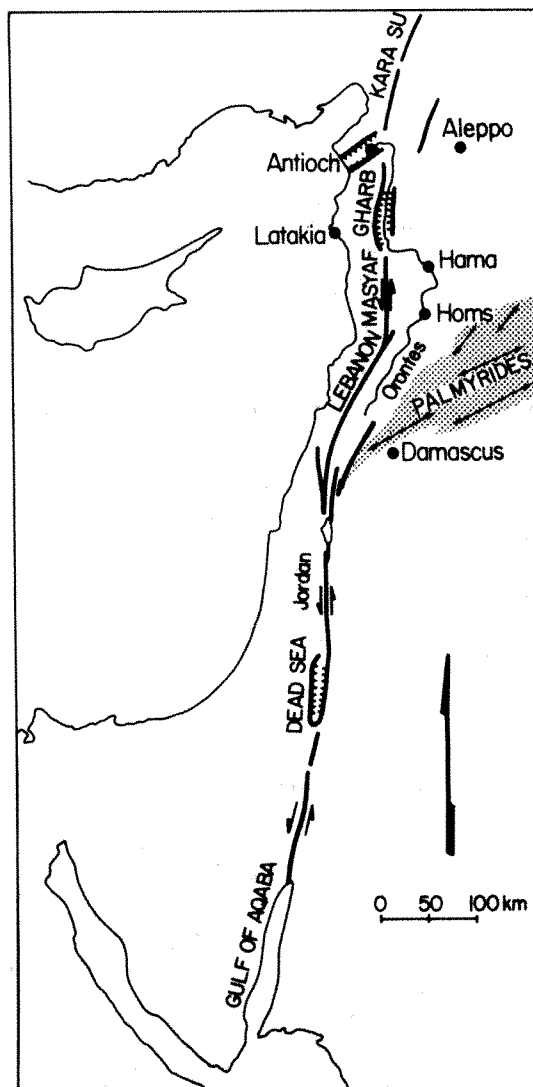
We can now estimate M_0^{max} from Molnar's formula, assuming reasonable values for the parameters β, μ, l, L and $\bar{V}$.


Fig. 1 Simplified map of the Dead Sea–Syrian faults system.

Table 1 Historical and instrumental seismicity

Date (AD)			I_0	M_L
52	Antioch	Destructions	VIII–IX	
115	Antioch	Heavy destructions	X–XI	
340	Antioch	Heavy destructions	IX	
394	Antioch	Heavy destructions	IX	
396	Antioch	Heavy destructions	IX	
458 September	Antioch	80,000 victims	IX	
526 May 29	Antioch	Very severe earthquake	IX–X	
528 November 29	Antioch	A mountain fell into the Euphrates at Quludhya, the Euphrates shifted its bed	X–XI	
581	Antioch	The suburb Daphne was destroyed	VIII–IX	
588 October 31	Antioch	Destroyed, 60,000 victims	IX	
634	Aleppo	Ramparts and fortress destroyed	VIII	
713 March 20	Antioch	Completely destroyed	IX	
859 December	Antioch	1,500 houses destroyed, 90 towers fell from the ramparts, Jebel al Aqra' (Bald mountain or Mons Casius 30 km SW of Antioch, close to the sea, 1,759 m high) "fell into the sea". A river disappeared into the ground; Urfa, Adana, Tarsus, Misis, Homs, Damascus destroyed	X–XI	
951 September	Aleppo	Heavy destructions, Ra'ban, Duluk (fortress between Aleppo and Antioch) destroyed	VIII–IX	
972	Antioch	Emperor Johannes Shamshik send 12,000 workers to rebuild the city	IX	
1002	Syria	Border zone, many destructions	VIII–IX	
1063 July	Antioch	Latakia, Tripolis, Acre	VIII	
1091 September 17	Antioch	70 towers fell from the ramparts	IX	
1139 November	Aleppo	Destroyed, evacuated by the inhabitants "The earth shook and the stones shook like grain in the winnowing basket"	X–XI	
1156–1159	Orontes	Aleppo, Hama, Afamya (Apamea), Shayzar (Larissa) Homs (Emessa)	IX–X	
1170 June 30	Aleppo	Totally destroyed, 80,000 victims; Damage in Orontes Valley	IX–X	
	Antioch	St Peters cathedral collapses over the patriarch		
1343 January 1	Membij	Destroyed, 5,700 victims, Aleppo fortress destroyed	IX	
1404 February 11	Aleppo	Heavy destructions, Latakia fortress destroyed	IX	
December 5	Aleppo	Three shocks	VII	
1408 December 30	Antioch	Heavy destructions, the ice fell off the top of Jebel al Aqra'	X–XI	
	Aleppo	Heavy destructions. Fissure 1 mile long in the neighbourhood (between al Qucir and Saltuhum)		
	Latakia	Sea wave		
1822 August 13	Antioch	Aleppo destroyed at 60% Sea wave at Iskenderun	X–XI	
September 5	Aleppo	Destruction of what remained, 20,000 victims		
1872 April 2	Antioch	Destroyed at 30%, 500–1,800 victims		
1936 June 14	Epicentre	near Antioch (36.5° N, 36° E)	VII	5.5
1951 April 8	Epicentre	near Antioch (36.6° N, 36°3E)	VII	5.7
1971 June 29	Epicentre	100 km of Aleppo (37.2°N, 36.8°E)		5
July 11	Epicentre	100 km of Aleppo (37.1°N, 36.9°E)		5

We take $\beta = 0.61$ from the empirical relationship found by Chinnery and North[10] for the whole world:

$$\log N = 17.47 - 0.61 \log M_0$$

where $N = 1/T$ is the frequency of the earthquakes having a seismic moment $\geq M_0$. This relationship is the same as the one on which Molnar's formula rests: $N = \alpha M_0^{-\beta}$, with $\beta = 0.61$.

We take the usual value for the rigidity of the crust: $\mu = 3.3 \times 10^{11}$ dyn cm^{-2}.

The depth l of the strike-slip faults is the depth of the brittle crust. Crustal structure studies by Ben Menahem et al.[11] in the Jordan area give $l = 20$ km. We will adopt this value.

We will take for L, the length of active fault, the total length of the fault system north of Lebanon, including the Karasu fault: $L \approx 300$ km. Although the fault system becomes more diffuse in the Antioch area this does not prevent us applying the formula[9].
Fig. 2 Spectrum of the intensity of earthquakes in North-west Syria from the first century AD to present. The Mercalli modified intensity in the epicentral zone has been assigned from the description of damage and ground deformation (summarized in Table 1).

The value of $\bar{V}$ relative displacement velocity along the fault (rate of slip) can be calculated from the present day relative motion of the Arabic and African plate given by Minster and Jordan[12]; their results were obtained by inverting data for the whole world (among which the Red Sea and Gulf of Aden rates of expansion): the value found, $\bar{V} = 1.2$ cm yr^{-1} is probably a little high, as part of the displacement along the transform fault is absorbed by deformation of the Lebanon and the Palmyrides and by some aseismic slip[11]. We will take $\bar{V} \simeq 1$ cm yr^{-1}. (On geological evidence, Freund et al.[6] have found a value for V of the order of 0.5 cm yr^{-1} in the Dead Sea region).

The uncertainties in these parameters and in the recurrence interval make up those inherent to Molnar's formula (which we will not take into account) to make our estimate of M_0^{max} rather vague.

Assuming that the minimum value of M_0^{max} corresponds to: $T_1 = 279$ yr, $l = 10$ km, $\bar{V} = 0.5$ cm yr^{-1} and the maximum value to the choice: $T_1 = 403$ yr, $l = 20$ km, $V = 1.2$ cm yr^{-1}, we find:

$$5.4 \times 10^{26} \leq M_0^{max} \leq 3.7 \times 10^{27} \quad \text{dyn cm}$$

We can apply Kanamori's formula[13]:

$$M_w = \frac{\log M_0}{1.5} - 10.7$$

We obtain for the largest earthquakes recurring at the rate of one every 341 ± 62 yr:

$$7.1 \leq M_w \leq 7.7$$

The preferred value corresponds to $T_1 = 341$ yr, $l = 20$ km, $\bar{V} = 1$ cm yr^{-1}; it is:

$$M_0 \simeq 2.6 \times 10^{27} \quad \text{dyn cm}$$

$$M_w \simeq 7.6$$

Having an estimate for M_0^{max}, we can now estimate the seismic moment of the smaller earthquakes with a recurrence interval $T_2 = 71 \pm 51$ yr. We find:

$$2.5 \times 10^{25} \leqslant M_0 \leqslant 4.9 \times 10^{26}$$

or

$$6.2 \leqslant M_w \leqslant 7.1$$

with a preferred value:

$$M_0 \simeq 2 \times 10^{26}$$

$$M_w \simeq 6.8$$

This agrees with the figure given by Ben Menahem *et al.*[11] for the Jordan Valley where they find an average of two events per century at magnitudes from 6 to 7.

Our catalogue of local seismicity and the application of Molnar's formula suggests that there are two different recurrence interval for earthquakes in North-west Syria due to the operation of the Syrian fault system: Earthquakes with $M_w \simeq 7.6$, the largest for the region have an average recurrence interval of 341 ± 62 yr; smaller earthquakes with M_w between 6 and 7 occur with a recurrence interval of 71 ± 51 yr. The last large earthquake occured in 1822, the next one is, therefore, not due for at least one century. On the other hand, as there has been no destructive earthquake since 1872, we forecast that an earthquake with a magnitude between 6 and 7 should occur soon.

Sinistral movement along the Gulf of Aqaba — its age and relation to the opening of the Red Sea

Y. Bartov & G. Steinitz

Geological Survey, Jerusalem, Israel

M. Eyal & Y. Eyal

Department of Geology & Mineralogy, Ben-Gurion University, Beer Sheva, Israel

The Red Sea forks northwards into the Suez Graben and the Dead Sea Arava Rift (Fig. 1). The southern part of the latter, about 165 km long, is occupied by the Gulf of Aqaba (Elat). A sinistral strike-slip movement of about 107 km which was suggested to have occurred along the Dead Sea–Arava Rift[1-3] is related to the opening of the Red Sea proper[1,4-6]. The opening of the Red Sea was considered to have taken place in two stages. The various dates proposed for the first movement are: from 41 to 34 Myr (ref. 5), from 29 to 24 Myr (ref. 7) and from 20 Myr onwards[6]. The second movement is generally dated from 4–5 Myr to Recent. Garfunkel and Bartov[8] claimed that the rifting in the Gulf of Suez was well under way in the span of the late Oligocene to early Miocene (30–20 Myr) and that a drastic change in the tectonic regime occurred in the middle Miocene (15—16 Myr). We suggest here, however, that the opening of the Red Sea is younger than 19–22 Myr.

Initiation of faulting within the Gulf of Aqaba[9] is assumed to predate the Neogene Raham Conglomerate which was deposited in a morphotectonic depression with structural relief exceeding 1.2 km. It was suggested that the first stage of horizontal movement began in the Mesozoic and resulted in a total displacement of about 60 km, and that a further movement of about 40–45 km was of post-Miocene age[10]. Freund and Garfunkel[11] suggested that the first stage of slip along the Dead Sea occurred in the early Miocene or earlier, and the second stage in the late Miocene or in the Pliocene. A different approach[12] suggested that the whole 107-km shear along the Dead Sea–Arava Rift may have occurred in the middle Miocene or later.

A belt of anastomosing faults was mapped by various investigators[3,13,14] in eastern Sinai, along the Gulf of Aqaba. This belt is part of the Dead Sea–Arava Rift Valley system. Small sinistral displacements, from hundreds of metres to several kilometres, were reported in this belt[3,11,13,15-17] based on offsets of lithological contacts in the Precambrian terrain or on geometric considerations pertaining to deformed strata of the sedimentary cover (Cambrian to Eocene). Freund and Garfunkel[11] suggested that these faults were active primarily, or only during the first stage of slip. Eyal[13] and Ben-Avraham *et al.*[18] noted that these faults did not participate in the youngest movements. Young faulting in this sector of the Rift is recorded only from within the Gulf and its shores[18]. In the present study we attempt to define more precisely the shear and its age along the western margin of the Gulf of Aqaba. This is a continuation of dating the movement on the Central Sinai–Negev Shear Zone[12,19].

Long basalt and olivine basalt dykes, trending SE–NW have recently been identified in southern Sinai (Fig. 1). These dykes are up to 100 m wide, tens to hundreds of kilometres long and are spaced several tens of kilometres apart. Some intrude Mesozoic sediments. They are similar to Tertiary igneous rocks which have been described in the Eastern Desert of Egypt[20-22], the Gulf of Suez[8], Central Sinai[19] and Saudi Arabia[23], all of which are considered to be of Miocene age based on field relations and K–Ar dating[12,24-26]. The dykes in southern Sinai have been dated by the K–Ar method. Results on five bodies yield ages of intrusion of 18–22 Myr which is a distinct and widespread volcanic phase in the Red Sea area.

Figure 1 presents the fault pattern along the Gulf of Aqaba. Most of the faults are in the form of lineaments within the Precambrian terrain. The general trace of the fault belt along the Gulf is of arcuate form.

The amount of sinistral movement along these faults was determined by offsets of magmatic bodies and lithological contacts in rocks of Precambrian age. These offsets were compared with offsets of the early Miocene dykes, on the same faults. In the areas where detailed mapping was undertaken identical displacements were recorded by both groups of markers.

In area A (Fig. 1) near Bir Zreir, the total cumulative displacement across the whole fault belt attains some 24 km. In most cases the amount of displacement on single faults is 0.8–4.0 km. The largest sinistral displacement recorded on a single fault in this area is 9.8 km. As the amounts of displacement measured on the Precambrian markers are in good agreement with those indicated by the early Miocene dykes, we suggest that the total 24 km of shear along this fault system postdates the early Miocene volcanic phase.

Faults showing a similar geometric pattern are recognized on the LANDSAT images of the Saudi coast of the Gulf of Aqaba
Fig. 1   Early Miocene volcanism and the Tertiary to Recent fault pattern in Sinai and adjoining areas. A, Bir Zreir area.

(Fig. 1). Some of these were mapped by Bramkamp *et al.*[27], Bender[28] and Freund *et al.*[3]. The amount of sinistral movement which is observable along these faults is at least some 18 km (based on displaced Precambrian elements that could be traced on the LANDSAT images). It is assumed that the total sinistral movement along the eastern side of the Gulf is approximately the same as that observed along the western margins of the Gulf of Aqaba. Thus only about 60 km of the total 100–105 km movement has been taken up by faults within the Gulf itself.

The analysis of the fault belt area along the Gulf of Aqaba suggests that the intrusion of very long basaltic dykes in a NW–SE direction, parallel to the coasts of the Red Sea and the Gulf of Suez, accompanied the initial stage of the development of the Red Sea. The igneous activity can probably be related to the faulting which led to the clear demarcation and subsidence of the Suez Graben[8] and the Red Sea[29]. Furthermore, some of the magnetic anomalies recorded in the Red Sea and in areas marginal to the Red Sea[30] may be related to such dyke intrusions.

A drastic change in the geotectonic regime occurs after the intrusion of the early Miocene dykes. We suggest that the large-scale horizontal movements (107 km) recorded along the Dead Sea–Arava Rift, postdate the intrusion of the early Miocene dykes, that is, are younger than 19–22 Myr. The movement along the Dead Sea–Arava reflects the seafloor spreading in the Red Sea. The age relations proved for the Dead Sea–Arava Rift imply that the opening of the Red Sea is also younger than 19–22 Myr.

Several authors have tried to relate the tectonic pattern of Israel and adjacent countries to the horizontal shear along the Gulf of Aqaba–Dead Sea Rift[4,31,32]. Considerable pre-Miocene tectonic activity is known along the Syrian Arc system[33]. Because of the age differences this activity cannot be considered as resulting from the shear along the Dead Sea–Arava Rift. This does not exclude the possibility that elements of the Syrian Arc and the Dead Sea Rift may have shown some slight initial activity as early as the Senonian [34,19].

Future work aimed at defining and correlating individual Neogene basaltic bodies on both sides of the Rift could help to establish an exact fit across the Rift.

Marine palaeotemperature studies are increasingly using oxygen isotope analyses of the minute calcium carbonate structures produced by a group of marine phytoplankton, the coccolithophores[1–6]. To provide a sound experimental basis for palaeotemperature calculations using the isotopic data from analyses of coccoliths, we have grown coccolithophores in laboratory batch culture in controlled environmental conditions, and determined the oxygen isotopic compositions of the coccoliths produced at known temperatures. The results reported here indicate that the oxygen isotopic composition of the coccoliths of all the species studied is strongly temperature dependent. A 'vital effect' was observed in all the species, with the isotopic values of different culture samples falling into two definite groups containing separate taxa. The difference in vital effect between different species suggests that calcification processes may vary among different taxa and indicates that a re-evaluation of coccolith oxygen isotope palaeoclimatic interpretations may be in order.

Coccolithophores possess certain unique advantages for oxygen isotope palaeoclimatic studies. As phytoplankters, they are restricted to the photic zone, with maximum population densities found between 50 and 100 m depth in most oceanic areas[7]. Consequently, coccolith secretion takes place only at near-surface water temperatures. On the other hand, planktonic foraminifera may produce their tests at the various temperatures found between the surface and depths as great as 1,500–2,000 m, although depth ranges for individual taxa may be more narrowly restricted[8]. In addition, coccolithophores show a wide geographic distribution, being found in all but polar seas[7]. Finally, coccoliths are more abundant than foraminiferal tests in many Tertiary and Cretaceous marine sediments[9].

We have maintained in laboratory culture the previously isolated *Emiliania huxleyi*, and successfully isolated and cultured for the first time *Gephyrocapsa oceanica*, *Cyclococcolithus leptoporus*, and *Thoracosphaera heimii*. These four species produce coccoliths frequently encountered in many Pleistocene and Holocene sediments.

The clonal algal cultures were grown in continuous batch culture and acclimated for 2 to 3 weeks at each temperature (12, 16, 20, 24, and 28 °C) before the coccoliths of the last batch culture were collected for analysis. The cultures were grown in 33‰ seawater enriched with *f*/2 levels of nutrients as described by Guillard[10] with silicic acid omitted. Light was provided by cool white fluorescent bulbs producing 0.023 langley min⁻¹. Coccoliths were concentrated by centrifugation in buffered distilled water, then oven dried and roasted under vacuum at 400 ± 25 °C to remove residual organic matter. The carbonate samples were reacted at 50 °C according to the method developed by Shackleton[11,12] and analysed by mass spectrometry. Samples of the water of the growth medium were analysed according to the method of Epstein and Mayeda[13] and corrections made according to Craig[14,15].

Analytical data obtained from over 70 samples showed two important trends. The $\delta^{18}O$ values of the coccoliths of *G. oceanica* and *E. huxleyi* are strongly temperature dependent

(Fig. 1), but are ~1‰ positive (enriched in ^{18}O) relative to calcium carbonate precipitated at equilibrium. The $\delta^{18}O$ values obtained from coccoliths of *C. leptoporus* and from tests of *T. heimii* also show a strong temperature dependence but are ~2.5‰ depleted in ^{18}O relative to equilibrium (Fig. 1). The isotopic compositions of these latter species are similar to values reported for coccoliths of *Cricosphaera carterae*[5]. Cultures of *G. oceanica* were maintained under both 14:10 hour light/dark cycles and 24-h light regimes. The $\delta^{18}O$ data on this species (Fig. 1) indicate no significant difference in oxygen isotopic composition related to the period of illumination.

The experimental data show a temperature dependence in oxygen isotopic composition which in no case corresponds to equilibrium precipitation of calcium carbonate. This would indicate that in all the coccolithophore species studied, a not unexpected vital effect influences the fractionation of oxygen
Fig. 1 The species plotted are *E. huxleyi*, 14:10 h light/dark cycle (+); *G. oceanica*, 14:10 h light/dark cycle (O), 24-h illumination (●); *C. leptoporus* 14:10 h light/dark cycle (□). *T. heimii*, 14:10 h light/dark cycle (X); and *C. carterae*[5], 12:12 h light/dark cycle (△). Each datum point represents an individual unialgal batch culture. The isotopic composition of the coccoliths are reported as $\delta_C - \delta_W$ versus temperature, where $\delta_C = \delta^{18}O$ of the coccoliths (‰ deviations from the PDB standard), and $\delta_W = \delta^{18}O$ of the water of the growth medium (‰ deviation from SMOW). The equations representing the least squares fit to the combined data of *E. huxleyi* and *G. oceanica* is $y = 3.68 - 0.17T$, ($r = 0.91$), and for *C. leptoporus*, *C. carterae*, and *T. heimii* is $y = 0.09 - 0.16T$, ($r = 0.87$).

isotopes during the secretion of the mineral. Isotopic analyses of both planktonic and benthonic foraminifera[16-19] have shown that their tests may be secreted out of isotopic equilibrium. In addition, the secretion of calcium carbonate in echinoderm tests and spines[20] and in parts of corals[21] has been found to reflect non-equilibrium conditions. Calcification in the coccolithophores is intracellular[22] in that coccoliths are produced inside each cell and extruded to the cell surface. Paasche[23] determined that bicarbonate rather than carbonate ions are used as a primary source of carbon in coccolith formation, further demonstrating that the deposition of calcium carbonate by coccolithophores is fundamentally different from any inorganic precipitation process. Therefore, comparison with products of extracellular calcification as described above can be made only with some reservation. The vital effect in the coccolithophores may reflect isotopic discrimination effects by cell membranes, as well as by the incorporation in the calcite of metabolic CO_2 or

photosynthetic O_2. Much work obviously remains to be done to understand the process of calcification in these planktonic algae. Relatively little is known about pathways, although our data do imply that calcification processes in coccolithophores may vary among different taxa. This is further suggested by the close grouping of the isotopic data for *E. huxleyi* and *G. oceanica* (Fig. 1), as these two species are thought to lie in a phylomorphogenetic lineage[24].

Recently, several investigators[3,4] have published analyses of 'bulk' carbonate samples composed of mixtures of different coccolith species and small foraminiferal tests. The isotopic signal recorded in such samples is a complex mixture of the isotopic signals of the different species comprising the bulk sample. Apparently the isotopic signal cannot be interpreted without data on the vital effect of each species included.

The presence of a vital effect in the fractionation of oxygen isotopes in coccolithophores does not preclude the use of coccoliths for oxygen isotope palaeotemperature analysis, as long as the magnitude of the effect is known over the temperature range in question. Nanofossil assemblages composed of coccoliths of *E. huxleyi* and *G. oceanica*, both of which are small, may be separated by settling and filtering techniques, and analysed for the oxygen isotopic composition. The $\delta^{18}O$ values of such an assemblage reflect the temperature and the $^{18}O/^{16}O$ ratio of the water in which these coccolithophores lived, even though the mineral was not precipitated in equilibrium. Factors such as light intensity, nutrients, and salinity may also play a role in regulating fractionation. These variables and their effect on isotopic composition are being examined in our laboratories.

Our increased understanding of the vital effect in the fractionation of oxygen isotopes by coccolithophores should increase the value of coccolith oxygen isotopic data in palaeoclimatic studies. The $\delta^{18}O$ data from coccoliths used in conjunction with oxygen isotopes data from foraminifera should allow us to determine with greater reliability variations in surface water temperature during the Pleistocene.

Note added in proof: The taxonomic position of the Thoracosphaerae, that is, whether they are coccolithophores or dinoflagellates, has been a matter for debate. Based on detailed examination of cell ultrastructure and particularly the presence of a typical dinoflagellate nucleus, we have concluded that *Thoracosphaera heimii* is a dinoflagellate and not a coccolithophore (L.E.B., P.L.B. and R.L.G., manuscript in preparation).

Early Jurassic plesiosaurs from Australia

Richard A. Thulborn

Department of Zoology, University of Queensland, St Lucia, Queensland, Australia 4067

Anne Warren

Department of Zoology, La Trobe University, Bundoora, Victoria, Australia 3083

Remains of plesiosaurs (aquatic reptiles of the suborder Plesiosauria, order Sauropterygia) are known from Cretaceous sediments in every continent[1], including Antarctica[2]. Jurassic plesiosaurs, by contrast, seem to have had a more restricted distribution, and are virtually unknown outside the Northern Hemisphere. We report here the discovery of two plesiosaur specimens in the Lower Jurassic of the eastern part of the Surat Basin, Queensland. These are the earliest adequate examples of plesiosaurs to be discovered in the Gondwana continents, and they greatly extend the known geographical range of early sauropterygians.

The specimens were collected from the upper part of the Evergreen Formation on Kolane property, about 60 km northeast of Wandoan, south-east Queensland. At Kolane, the Evergreen Formation is represented by ferruginous sandstones, thick seams of concretionary ironstone, and argillaceous oolites; these beds are probably an eastwards extension of the Westgrove Ironstone member, as identified towards the top of the Evergreen Formation in the western parts of the Surat Basin[3,4]. The upper part of the Evergreen Formation has been dated as Upper Liassic on the evidence of plant microfossil assemblages[3,4]. As well as plesiosaurs, the Kolane locality has yielded poorly preserved plant remains, thin-shelled lamellibranchs, and an almost complete skeleton of the last-known labyrinthodont amphibian[5].

The less complete of the two plesiosaur specimens (Queensland Museum catalogue no. F10440) is preserved in sandstone and oolite, and comprises a scattering of fragments apparently derived from a single skeleton. The bones are severely weathered, but include recognizable portions of limbs and girdles, and vertebrae bearing rib attachment scars of distinctive plesiosaurian type (Fig. 1a). The specimen is certainly a plesiosaur, but it is so incomplete that its more immediate relationships cannot be determined.

The second specimen (QM F10441) was found about 400 m north of the first, and about 10 m above the site of the Kolane labyrinthodont. It is preserved in blocks of concretionary ironstone, so that its development may present difficulties. This specimen seems to be part of an articulated skeleton, and includes vertebrae, ribs, girdle bones, limb bones and, possibly, gastralia; no cranial elements have been identified with certainty. Two of the cervical vertebrae are exposed on a broken surface and show diagnostic plesiosaurian features allowing identification down to family level (Fig. 1b). Such identification is admissible because detailed studies of vertebrae form the basis of plesiosaur classification[1,6]. Each cervical centrum is roughly cylindrical, with a fairly flat ventral surface and weakly depressed terminal faces. The floor of the neural canal forms a shallow groove in the dorsal surface of the centrum, so that the latter is slightly kidney-shaped in cross-section. On the ventral surface the large nutrient foramina are separated by a flat area. The standard height/length and width/length indices (ratios × 100) for these cervical centra are about 95 and 115, respectively. Other vertebrae show that the rear margin of each neural spine is vertically grooved—a distinctive feature noted by Welles[6] in elasmosaurid plesiosaurs, and illustrated by Owen[7] in plesiosaur vertebrae from the English Lias. A damaged cervical rib seems

originally to have been of characteristic 'hatchet shape'. Structure and proportions of these cervical vertebrae clearly indicate that specimen F10441 is a dolichodiran (or long-necked) plesiosaur, almost certainly referable to the family Plesiosauridae (part of the superfamily Plesiosauroidea).

There are few records of plesiosaurs from Jurassic or earlier rocks of Gondwanaland. The report of a 'suspected plesiosaur' in the Upper Triassic of New Zealand[8] is founded on a single fragment of limb bone; this fragment could equally well have come from some other type of reptile, or even from an amphibian (see account by W. E. Swinton in ref. 8). A single vertebra from the Upper Liassic of Argentina was originally attributed to a crocodile[9], but was identified by von Huene[10] as plesiosaurian; Welles considered[6] that this specimen was not diagnostic. Other records of plesiosaurs from the Jurassic of Argentina[11,12] are erroneous or founded on indeterminate material[1,6,13]. Isolated skull fragments of pliosaurs (plesiosaur superfamily Pliosauroidea) are known from the Upper Jurassic of India[14] and Ethiopia[15]. Fragmentary pliosaur material was also reported by Bartholomai[16] from an early Cretaceous or late Jurassic conglomerate at Mount Morgan, Queensland.
Fig. 1 Plesiosaur vertebrae from the Evergreen Formation (Upper Liassic) of south-east Queensland. *a*, Two anterior caudal vertebrae (from specimen QM F10440) in left lateral view, showing neuro-central sutures (ns), crater-like scars for rib attachment (r) and prezygapophysis of second vertebra (pz). *b*, Two cervical vertebrae (from specimen QM F10441) in ventral view, showing large nutrient foramina, detached cervical rib (cr), and damaged area of rib attachment (r). Matrix is unshaded, and badly damaged surfaces are indicated by oblique shading. Both scales represent 2 cm.

The Kolane specimens are, thus, the earliest adequate examples of plesiosaurs from Gondwanaland. Their discovery greatly extends the known geographical range of early sauropterygians and implies that the Plesiosauria might have had an almost world-wide distribution as early as the Lower Jurassic. The association of the Kolane plesiosaurs with a labyrinthodont amphibian is, at the least, surprising: plesiosaurs typically occur in marine faunas of the Jurassic and Cretaceous, whereas labyrinthodonts are mainly known from continental faunas of the late Palaeozoic and Triassic. The occurrence of a plesiosaur

referable to the Family Plesiosauridae is consistent with the Lower Jurassic age of the Evergreen Formation, and tends to confirm that the labyrinthodont is a late survivor[5]. Reiser and Williams concluded[4] that most of the Evergreen Formation was laid down in continental conditions, but that the peculiar lithology of the Westgrove Ironstone member might be suggestive of a marine origin. Either the Kolane plesiosaurs were sea-dwellers, and the associated labyrinthodont was accidentally introduced into a marine environment, or the plesiosaurs were non-marine types, ecologically comparable with those, for example, of the English Wealden.

We thank Mr and Mrs Colin Kehl, of Kolane, and Dr Mary Wade, of the Queensland Museum. Financial support came from the Australian Research Grants Committee.

Kin preference in infant *Macaca nemestrina*

**Hannah M. H. Wu, Warren G. Holmes*,
Steven R. Medina & Gene P. Sackett**

Department of Psychology and Regional Primate Research Center, University of Washington, Seattle, Washington 98195

The ability to recognize conspecifics is a prerequisite for many types of social behaviour, including, for example, parent–offspring relations[1,2], mate selection and recognition[3,4], territorial defence[5,6] and dominance coalitions[7]. This ability is of special importance to Hamilton's kin selection hypothesis[8], which predicts that an individual's behaviour towards a conspecific will depend on the degree of genetic relatedness between them. Although recognition depends on previous experience between individuals in some species[1,2], this does not preclude the possibility that recognition could occur in its absence[12]. For example, juveniles who disperse before non-littermate siblings are born or adult males who do not participate in rearing their young might benefit from recognition abilities that are independent of prior association between the individuals. Here we show that young pigtail macaques prefer to interact with a related over an unrelated monkey in a laboratory test. Because subjects were separated from their dams at birth and reared apart from all other relatives, results suggest that kin recognition can occur in the absence of prior association with relatives.

* Present address: Department of Psychology, University of Michigan, Ann Arbor, Michigan 48109.

Subjects were 16 infant pigtail macaques (*Macaca nemestrina*) of known genealogies from a captive breeding colony (Table 1). Taken from their dams within 5 min of birth, subjects were placed in an incubator until they became homeothermic and were then transferred to a colony room (7.6 m × 11.0 m) and housed individually in wire cages. Subjects were placed in this room housing 50 other monkeys such that they had no opportunity for visual, physical or olfactory interactions with relatives or any other animals used in the experiments. To ensure normal social development, subjects interacted daily in 'play groups' with four to six similarly aged monkeys, none of whom was related to the subjects.

The Sackett self-selection circus (Fig. 1) was used to measure preference in a free-choice situation. Thus, subjects could select among three simultaneously presented stimuli by first visually orientating towards each one, and later entering the compartment to which a stimulus was attached, orientation time and entry time serving as two measures of preference. Orientation and entry time were recorded by an observer who viewed subjects from a separate room on a closed-circuit television and who knew nothing of the monkeys' genetic relationships.

Subjects were tested once in two different experiments, each using an identical testing procedure but with a different set of choice stimuli. Experiment I offered choices among a subject's paternal half-sibling, an unrelated (to both the subject and other stimulus animal) monkey, and an empty cage to examine our hypothesis that subjects would prefer their relative. Stimulus animals were matched by sex, age, weight, and general activity level and appearance (as subjectively judged by us). Both the subject's half-sibling and unrelated conspecific were delivered and reared identically to the subject. Experiment II examined the strength of the preference predicted in experiment I by providing choices among the subject's paternal half-sibling from experiment I, a 'preferred nonrelative', and an empty cage. The

Orientation of subject and and stimulus monkey
Fig. 1 The Sackett self-selection circus, used in several other studies to measure social preference in primates[9], was constructed of movable, transparent Plexiglass panels separating the apparatus into a central start compartment and six choice compartments, three of which were used. Plexiglass-carrying cages, each holding the appropriate stimulus, were attached randomly to non-adjacent choice compartments before a subject was placed in the start compartment. Subjects were adapted to the circus before testing. Each subject's preference for the three stimuli was measured during a 15-min test. During the 5-min orientation period when the subject was confined to the start compartment, its visual orientation times, scored whenever its head and body were orientated towards choice stimuli, were recorded by a trained observer (S.R.M.). The observer viewed subjects from a separate room on a closed-circuit television and knew nothing of the monkey's genetic relationships. The start compartment panels were then raised by remote control, and the subject allowed 10 min of unlimited access to the three choice compartments (and start compartment), where it could interact in all ways with the stimulus monkeys except by making physical contact. Entry time elicited by each stimulus was recorded and defined as the total time the subject spent in a particular choice compartment. Subjects typically entered each compartment more than once and also spent time in the start compartment.

preferred nonrelative was obtained for each subject in a separate choice experiment in which two matched stimulus animals, both unrelated to the subject, were presented as choice stimuli. The animal eliciting the greatest amount of entry time was defined as the preferred nonrelative.

Subjects' performances and relevant variables are summarized in Table 1 and Fig. 2. In experiment I, a significant number of subjects (13 of 16) exhibited more entry time toward half-siblings than toward unrelated animals ($P \leq 0.01$, binomial test) and a significantly greater amount of entry time towards half-siblings than towards unrelated animals ($P \leq 0.05$, Wilcoxon signed-ranks test) (Fig. 2a). Subjects' orientation time towards half-siblings was also greater than towards unrelated animals, but this difference was not significant ($P \leq 0.1$). There was no significant correlation between subjects' age and relative kin entry time (kin/total entry time), a measure that controls for developmental differences in mobility. In experiment II, half-siblings elicited more entry time and more orientation time than unrelated animals, although neither of these differences were significant ($P < 0.1$ and $P \leq 0.1$, respectively) (Fig. 2b).

Based on orientation and approach toward half-siblings in experiment I, we conclude that infant pigtail macaques prefer to interact with their half-siblings rather than nonrelatives and, therefore, can discriminate between them. Furthermore, based on rearing conditions of both subjects and stimulus animals, we conclude that this preference and discrimination ability require no previous experience with relatives. Because half-siblings were paternally related, common prenatal experience cannot explain preferences. Of course, each subject experienced itself during rearing which, in some sense, could be considered experience with a relative. And experience with one's own phenotype has been suggested as the basis for demonstrated social preferences in domestic chicks reared in isolation[10].

The data provide no evidence for the proximal basis of the discrimination ability, but results from visual orientation time imply something about the significance of visual cues. Thus, 14 of 16 stimulus animals eliciting the greatest amount of orientation time in experiment I were also favoured in entry time, suggesting that subjects had established preferences even before they were allowed into choice compartments.

Fig. 2 Mean entry and orientation time (±s.e.) elicited by various choice stimuli in experiment I (a) and experiment II (b) ($n = 16$ for each bar). Orientation and entry times were used as two measures of subjects' preference for the choice stimuli during the initial 5-min and the following 10-min periods, respectively. Statistical comparisons (see text) were made with the Wilcoxon signed-ranks test; 1-tailed tests were used based on predicted preferences for half-siblings.

Hamilton argued that selection favours individuals assisting others in proportion to genes shared in common, other things being equal. Although a laboratory study[11] has shown that aiding is directed along lines of genetic relatedness among pigtails reared together, our data are clearly insufficient to demonstrate kin selection. Furthermore, we do not suggest that social preferences would be unaffected by experience; pigtails do prefer a familiar conspecific to an unfamiliar one[9]. Finally, although our results are based on a single age-class in one species, they do heed us to examine the frequent assumption that recognition of kin requires prior association among relatives.

We thank the members of the Animal Behavior Seminar for helpful discussions, and D. Barash, C. Crockett, W. D. Hamilton, R. Holm, J. Lewis, J. Lockard, G. Orians, G. Ruppenthal, P. Sherman, W. Stimulation of the cerebral cortex in the intact human subject

P. A. Merton & H. B. Morton

The National Hospital, Queen Square, London WC1N 3BG, UK

One of the most fertile methods of investigating the brain is to stimulate a part of it electrically and observe the results. So far, however, use of the method in man has been restricted by the necessity of opening the skull surgically to apply the electrodes. Much could be done, both with healthy subjects and with neurological patients, if it were feasible to stimulate through electrodes on the scalp, although the localization of the stimulus on the cortex will always be much less sharp than with electrodes on the brain surface. In an intact man, however, the brain is protected from electricity by the skull and by the scalp, both of which normally offer considerable resistance. Furthermore, the cerebral cortex does not have a particularly low electrical threshold. It is probably for these reasons (despite an occasional contrary claim[1]) that attempts to stimulate the brain by applying stimuli from conventional stimulators to the scalp have been stopped by pain or have otherwise failed. These obstacles have now begun to yield. Recently, it was found that, on stimulating muscles in the human hand[2] without any special preparation of the skin, the effective resistance fell to low values if brief but very high voltage shocks were used. Applying the same technique to the head, it has now proved possible at the first attempt to stimulate two areas of the human cortex, without undue discomfort.

The stimulating electrodes were ordinary stick-on silver-cup electroencephalogram electrodes of 1 cm diameter, filled with electrode jelly. For the motor area, one electrode was applied initially over the surface marking of the arm area of the motor cortex and the other 4 cm in front. To stimulate, a 0.1-μF condenser charged to up to ~2,000 V was discharged through the electrodes using a Morse key. The electrode over the motor area was the positive. A shunt resistance of 100 Ω ensured that the time constant of discharge was less than 10 μs.
Fig. 1 Stimulation of the arm area of the motor cortex. The records shown are of action potentials from the contracting muscles in the forearm. Stimulation is at the start of the sweep. Four records are superimposed. The latency of responses was 16 ms. (Subject P.A.M.)

Stimulation showed itself by twitch-like movements of the opposite middle and index fingers, or, with the active electrode over the leg area, of the foot. In one subject (height 1.88 m), muscle action potentials recorded through surface electrodes over the active muscles showed fairly sharp latencies of 16 ms for the forearm muscles (Fig. 1) and 34 ms for the muscles in the lower leg. These values agree with those obtained by stimulating the exposed human motor cortex or the nerve fibres leaving it[3,4].

With electrodes on the back of the head, over the visual area of the cortex, illusory visual sensations ('phosphenes') were experienced. Larger voltages were necessary for the visual area than for the motor area. For each stimulus the phosphene was very brief. It appeared near the centre of the visual field as a patch, with indefinite edges, subtending some 5°, containing one or a few, sharp, bright sinuous lines. The main evidence that such phosphenes are caused by stimulation of the visual cortex is that they only occurred with electrodes over the visual area and that, within that region, the position of a phosphene in the visual field moved with the position of the stimulating electrodes in a manner that conformed with the known mapping of the visual field on the cortex (half-fields reversed and upside down, with a large area for the centre of the field on the occipital poles). Thus, with a horizontal pair of electrodes above the occipital pole (6 cm above the inion), the phosphene was below the fixation point. It moved upwards roughly to the fixation point when the electrodes were moved downwards (to 3 cm above the inion). Similarly, the phosphenes appeared mainly on the right with electrodes to the left of the mid-line, and vice versa. They disappeared altogether when the electrodes were moved away more than a few centimetres from the occiput.

Another important observation is that the phosphenes described did not disappear when the eyeballs were pressed on until sight was lost in both eyes, so they were not due to the excitation of the retina by spread of current. Such excitation occurs very readily, as the retina has a low electrical threshold; but the resulting phosphenes fill diffusely much of the visual field, are without structure, are not specially related to stimulation over the visual area, and disappear with pressure-blinding. Thus, although both may be seen simultaneously, phosphenes from current spread to the retina are readily distinguished from the phosphenes we attribute to stimulation of the visual cortex.

Fig. 1   Voltage homogeneity in the small A-V node specimen tested by three different microelectrodes. The current feeding electrode was positioned at the centre of the endocardial side and other two recording microelectrodes were applied about 50 µm from the edge of the preparation. *a*, Simultaneous action potential discharge at three different sites. Action potential measurements are: overshoot 21 mV, maximum diastolic potential −60 mV, duration of the action potential at 50% repolarization 68 ms, maximum rate of rise $10\,V\,s^{-1}$, firing frequency $196\,min^{-1}$. *b*, Evaluation of spatial clamp during the slow inward current by monitoring the potential outside the clamp circuit (lowest voltage trace). Holding potential −40 mV, test pulse −10 mV. 1, command pulse; 2, monitor potential; 3, current trace. *c*, Spatial clamp during the delayed current. Two potential traces were displayed at the same position on the scope. 1–3, As in *b*. Note the difference in calibration between *b* and *c*.

If the heart is to function as an efficient pump, there must be an adequate time delay between the contraction of the atria and that of the ventricles. A major part of this delay is provided by the time of conduction of excitation across the atrioventricular (A-V) node, which electrically links the ventricles with the atria. When the primary pacemaker in the sinoatrial (S-A) node fails to control the cardiac rhythm, as the result of either a depressed automaticity or an impaired conduction, the A-V node can become the pacemaker of the heart[1]. In spite of these essential physiological functions of the A-V node, the precise ionic bases of conduction and the automaticity in the A-V node tissue remain unclear. Here we demonstrate the slow inward current as well as the delayed potassium current in the A-V node using the two-microelectrode voltage-clamp technique.

Recently, DeMello[2] reported the space constant of the rabbit A-V node as 0.4 mm. This clearly indicates that voltage-clamp studies on this tissue are possible using specimens smaller than 0.2 mm. In the present study, small A-V node specimens from the rabbit heart were prepared in essentially the same manner as for the S-A node[3]. The A-V node was identified by its anatomical localization and the action potential configuration[1]. Small strands of tissue 0.2 mm wide and 1–2 mm long were dissected from the A-V node in a 36 °C Tyrode solution, with their longitudinal axis roughly perpendicular to the fibrous A-V ring. This thin strand was then ligated at two sites with a fine silk fibre (prepared by unwinding commercially available silk suture). to give a final dimension of 0.2 × 0.2 × 0.1 mm.

Most of these small A-V nodal preparations spontaneously discharged action potentials (Fig. 1*a*) which were quite similar to those reported previously[4–6]. Voltage homogeneity within this small specimen was tested by using three microelectrodes. Action potentials simultaneously recorded from three different sites (50 µm apart) were closely similar (Fig. 1*a*). During the voltage clamp, the membrane potential monitored outside the feedback circuit deviated only 5 mV for about 10 ms after the onset of the test pulse (Fig. 1*b*, *c*). Therefore, no serious deviation from the command pulse occurred. Similarly good results were obtained in one out of every five specimens tested with three microelectrodes.

Figure 2 shows a family of voltage-clamp records and the current–voltage relationships. The holding potential was −40 mV, where the steady net current was about 0. The transient inward current was recorded between −40 mV and +35 mV, with its peak amplitude at around −10 mV. At −10 mV, the peak of this inward current occurred 5–10 ms after the onset of the test pulse, and the current was inactivated with a time constant of 15–30 ms (Figs 1*b*, 3*a*). This slow time course of the transient inward current is quite similar to that of the slow inward current in the S-A node[7]. To identify this current, we superfused this specimen with compound D600 (Fig. 3*a*), which abolishes the slow inward current. The transient inward current progressively decreased and finally disappeared after 3 min. In contrast, tetrodotoxin, the fast Na^+ channel blocker, caused no appreciable change in the transient inward current. These

observations agree well with previous findings that the A-V node action potential was blocked by Ca-antagonists but not by tetrodotoxin[4–6,8]. Based on these findings, the upstroke of the action potential in our small A-V node preparation is considered to depend predominantly on the slow inward current. Action potentials in the S-A node were shown to propagate at a speed of $2-3\,cm\,s^{-1}$ (ref. 9), and a similar conduction velocity was reported for the A-V node[10]. Dependency of action potentials in these two structures on the slow inward current would readily explain such a slow conduction.

Delayed current systems in these small A-V nodal specimens were also similar to those found in the S-A node. Depolarization
Fig. 2   Current and voltage relationships in the A-V node. Closed symbols indicate transient current, open symbols show the current at 1 s after the change in the potential. Two different experiments are shown. Inset *a* (depolarization) and *b* (hyperpolarization) represent a family of voltage-clamp records in a specimen, from which the curves with triangles were obtained. Duration of the clamp pulse is 1 s.

caused a slow increase in the outward current, whereas on repolarization, a gradual decay in this current was observed (Fig. 2). The time course of this outward current tail within 1s was well fitted by a single exponential curve, with a time constant of 189 ± 24 ms (mean $\pm$s.d., $n = 6$). The reversal potential of the outward current was measured by recording the outward current tail at various potential levels. At 10 mM K^+, the outward current tail changed its sign at around -60 mV (Fig. $3b$),
Fig. 3 a, The slow inward current and its progressive decrease induced by perfusion of D600. Current traces from bottom to top were obtained in the control solution, and 1, 2 and 3 min after perfusion of 5×10^{-7} g ml^{-1} D600, respectively. b, c. Reversal potentials of the outward current tail at 10 mM (b) and 20 mM (c) extracellular K^+ concentrations. Top, membrane potential; bottom, current trace. The membrane was depolarized to -10 mV for 1 s and then repolarized to -40, -50, -60, and -70 mV in b and to -30, -40, -50 and -60 mV in c. The time constant of the tail current was 100–240 ms at -50 to -70 mV. At the control concentration of K^+ (3 mM) the reversal of the tail current could not be recorded because of a large inward-going rectification.

whereas at 20 mM K^+, it did so between -40 and -50 mV (Fig. $3c$). From the voltage relationship of the outward current tail, the reversal potential was determined as -62 mV and -43 mV at 10 mM and 20 mM K^+, respectively. Approximately the same slope of 61 mV per 10-fold increase in K^+ concentration was also obtained in three other experiments. These results suggest that K^+ ion is responsible for this outward current. The inward-going current change noted on hyperpolarization from -40 mV to -60 mV (Fig. 2) may be attributed to deactivation of the K^+ current. On the other hand, large inward current changes recorded with further hyperpolarization may be analogous to the current induced by a strong hyperpolarization in the S-A node[11] and in the frog sinus venosus[12]. It is possible that these delayed current systems are involved in the pacemaker depolarization, as is the case for the S-A node.

The present voltage-clamp study showed that the A-V nodal cells possess transmembrane current systems quite similar to those in the S-A node. A common ionic mechanism may underlie automaticity and slow conduction in these two small but vitally important nodal structures in the heart.

α₂-Adrenergic receptors appear in rat salivary glands after reserpine treatment

David B. Bylund & J. Ricardo Martinez

Departments of Pharmacology and Child Health, University of Missouri, School of Medicine, Columbia, Missouri 65212

The regulation of central and peripheral adrenergic receptors by various chemical, physiological, pharmacological and pathological stimuli has been the subject of intense study[1,2]. For example, drug treatments can produce relatively small changes in the density of existing receptor binding sites in a variety of tissues. The α-adrenergic receptors in rat salivary gland tissue have been studied using radioligand receptor binding techniques[3]. We have recently identified and characterised α_1-adrenergic receptors in the rat submandibular gland[4], but surprisingly, α_2-adrenergic receptor binding was not detectable. We now report that a single treatment of reserpine results in the appearance of α_2-adrenergic binding sites within 12 h. Continued treatment with the drug produces further increases in the number of α_2-adrenergic receptors, such that after 7 days the levels of α_1- and α_2-adrenergic receptors are similar. This is the first example of a drug treatment resulting in the appearance of a receptor type which was not previously detectable.

α-Adrenergic receptors, which are heterogeneous in many tissues, have been divided into α_1- and α_2-subtypes on the basis of the differential potency of certain drugs[5]. The α_1-adrenergic receptors are thought to mediate postsynaptic α-adrenergic effects of noradrenaline. In contrast, the α_2-adrenergic receptors generally appear to be involved in the regulation of presynaptic function, and may be localised on the presynaptic membrane. In the appropriate conditions, ^{3}H-clonidine specifically labels α_2-adrenergic receptors in membrane fractions of various mammalian tissues[6,7]. Using this radioligand, we have characterised the α_2-adrenergic receptors in the submandibular gland of control and reserpine-treated rats.

The specific binding of ^{3}H-clonidine to α_2-adrenergic receptors in glands from control animals cannot be reliably quantified (Fig. 1). However, after seven daily injections of reserpine (0.5 mg per kg, intraperitoneally) the amount of specific binding increased dramatically. Rosenthal analysis[8] of the data from a saturation experiment indicated a single class of high-affinity receptor binding sites, having a dissociation constant (K_D) of 1.1 nM (Fig. 1). The maximal number of receptors (B_{max}) that could be labelled by ^{3}H-clonidine in these conditions was 6.1 pmol per g wet weight of tissue. In contrast to this large increase in α_2-adrenergic receptors, α_1-adrenergic receptors

Table 1   Inhibition of ^{3}H-clonidine binding in submandibular gland membranes from reserpinised rats

Drug	n	K_i (nM)
(−) Adrenaline	7	2.6 ± 0.3
(−) Noradrenaline	3	2.9 ± 0.7
(+) Noradrenaline	1	200
Phentolamine	3	3.6 ± 0.4
Prazosin	5	$5,200 \pm 900$
Yohimbine	5	63 ± 14

IC_{50} values were determined from log-probit analyses of inhibition curves using 10 concentrations of the unlabelled drug in duplicate. The concentration of ^{3}H-clonidine was 0.70 nM (13,000 c.p.m.). K_i values were calculated from the equation $K_i = IC_{50}/(1 + [^3\text{H-clonidine}] /K_D) = 0.73\ IC_{50}$.

increased only 56% (from 5.3 to 8.3 pmol per g tissue) after 7 days of reserpine treatment[4].

This time course of the appearance of α_2-adrenergic receptor binding sites is illustrated in Fig. 2. At 12 and 24 h after a single injection of reserpine, the receptor levels were approximately 2 and 3 pmol per g tissue, respectively. When daily injections were continued for 2 to 7 days, the α_2-adrenergic receptor levels continued to increase, and reached a plateau at a level about double that found after a single injection. Although not presented, an identical type of curve was obtained when the data were calculated in terms of pmol bound per mg of membrane protein. The sites labelled by ^{3}H-clonidine in glands from animals treated for 7 days with reserpine have the pharmacological specificity and characteristics of α_2-adrenergic receptors (Table 1). This induction of α_2-adrenergic receptors is also fully reversible in that 2 days after cessation of chronic reserpine treatment, the levels of α_2-adrenergic receptors decreased by about 50% and by 5 days approached the undetectable levels in control animals (unpublished data).

A major pharmacological effect of reserpine is the depletion of presynaptic stores of noradrenaline, which in turn, results in a decreased concentration of noradrenaline in the synapse[9]. There is considerable evidence in both central and peripheral systems, that changes in the density of adrenergic receptors are inversely related to changes in the amount of noradrenaline available to interact with these receptors[1,2]. Thus, it is reason-able to propose that the appearance of α_2-adrenergic receptors in the submandibular gland is a result of the decrease in noradrenaline levels. However, the mechanism of the appearance of these receptors, whether by new synthesis or by the 'unmasking' of existing receptors, is not investigated in our studies.

Fig. 2 The effect of the duration of reserpine treatment on the apparent number of α_2-adrenergic receptor binding sites. Rats were treated daily with reserpine (0.5 mg per kg, intraperitoneally) and then killed 24 h after the last injection (the 0.5 day time point was 12 h after a single injection). The submandibular glands were removed and the B_{max} for ^{3}H-clonidine binding determined as in Fig. 1. Values plotted are means ± s.e.m. and the number of experiments is given in parentheses. Although not shown, there were no significant differences in K_D among the various time points. (The mean ± s.e.m. K_D was 2.05 ± 0.14 nM.)

Fig. 1 Rosenthal analysis of ^{3}H-clonidine binding in rat submandibular gland. Glands were removed from control rats (●), and from treated rats (O) 24 h after the last of seven daily injections of reserpine (0.5 mg per kg, intraperitoneally). The glands were homogenised (Tissumizer) twice in 20 volumes of ice cold 50 mM Tris (pH 8.0 at 25°) and centrifuged at 49,000g for 10 min following each homogenisation. The pellet (a crude particulate fraction) was suspended in 90 volumes of 50 mM Tris (pH 7.4 at 25 °C). For the binding assay, 970 µl of this suspension were incubated for 25 min at 23 °C with various concentrations of ^{3}H-clonidine (22.2 Ci mmol^{-1}, NEN). The suspensions were filtered through GF/B glass-fibre filters (Whatman), washed with buffer, and the radioactivity remaining on the filter was determined. Nonspecific binding, defined by parallel incubation tubes containing 10 µM (−)noradrenaline, was subtracted from the total binding to obtain specific binding. The final concentrations of ^{3}H-clonidine were from 0.08 to 13.3 nM. For the reserpinised animal, the values calculated from a least squares linear regression analysis are, $K_D = 1.1$ nM, and $B_{max} = 68$ pM or 6.1 pmol per g tissue or 146 fmol per mg protein. The means ± s.e.m. for eight experiments are $K_D = 1.9 \pm 0.3$ nM and $B_{max} = 6.2 \pm 0.9$ pmol per g tissue. A plot of this type is often mistakenly called a Scatchard plot. The Scatchard derivation[13] assumes a single species of binding macromolecule of known molecular weight and concentration. When these values are not known, as in the present case, where binding is to membrane fragments, it is appropriate to use the Rosenthal plot[8].

The reserpinised rat has been proposed as an animal model for the human disease, cystic fibrosis[10,11]. This hypothesis is the result of studies on rats treated chronically with reserpine which have demonstrated changes in exocrine gland morphology and function similar to alterations observed in patients with cystic fibrosis. Since abnormalities in the autonomic regulation of salivary and other exocrine glands may be a contributory factor in the aetiology of this disease[12], it will be of interest to investigate α_2-adrenergic function in cystic fibrosis patients.

These data show that the levels of α_2-adrenergic receptors in the rat submandibular gland can be regulated over a far larger range than has been demonstrated for any other neurotransmitter receptor. This system thus seems ideally suited for the study of the localisation, function and mechanisms of regulation of α_2-adrenergic receptors.

Changes of hippocampal Met-enkephalin content after recurrent motor seizures

J. S. Hong, P. L. Wood, J. C. Gillin*, H. Y. T. Yang & E. Costa

Laboratory of Preclinical Pharmacology and *Laboratory of Clinical Psychopharmacology, National Institute of Mental Health, Saint Elizabeths Hospital, Washington, DC 20032

Kainic acid (KA), a powerful neurotoxic analogue of glutamate, has been extensively used as a tool for selectively lesioning neuronal cell bodies; however, axons or nerve terminals are spared from damage in the area injected with kainic acid[1,2]. Injections of this neurotoxin in various brain regions were successfully used to locate cell bodies of neurones containing substance P, enkephalin and other putative neurotransmitters[3,4]. While attempting to locate the cell bodies of the enkephalin containing neurones present in hippocampus using KA injections, we found that a few days after intracerebral injections of KA a drastic increase in the Met-enkephalin (ME) content of hippocampus occurs. We now describe the delayed increase in hippocampal ME content elicited by intracerebral KA injections and examine the possible mechanism that is operative in causing this increase. Moreover, we provide some evidence suggesting that the increase in ME content elicited by intracerebral injections of KA may be related to the recurrent motor seizures elicited by intracerebral injections of KA.

Male Sprague–Dawley rats (Allison Park) weighing 180–200 g were used. The coordinates for intrahippocampal injection are: A, 3.5; L, 2.4; V, 2.5 according to the atlas of König and Klippel[5]. Unless otherwise stated, rats were anaesthetized with Equithesin (Jensen Salsbury) placed into a stereotaxic holder and injected at constant rate $(1 \ \mu l \ min^{-1})$ with KA dissolved in $1 \ \mu l$ of 0.9% NaCl. The concentration of ME in different brain regions was determined by a previously described radioimmunoassay method[6,7].

Unilateral intrahippocampal injection of KA $(1 \ \mu g$ in $1 \ \mu l$ of 0.9% NaCl) caused recurrent motor seizures lasting 4 to 6 h. ME levels in hippocampus and other brain regions were determined at various times after the injection of KA. At 6 to 12 h after the intrahippocampal injection of KA, the ME content in both injected and contralateral hippocampus was slightly lower than before the injection whereas at 24 h after injection the ME content was increased. In the side injected with KA this elevation reached a maximum after 2 to 3 days and lasted more than 2 weeks. In the hippocampus contralateral to the KA
Fig. 1 Time course of change in hippocampal Met-enkephalin content after intrahippocampal injection of kainic acid $(1 \ \mu g$ in $1 \ \mu l$ of 0.9% NaCl). $n = 6$; * significantly different from control, $P < 0.05$.
Fig. 2 Hippocampal Met-enkephalin content in control and kainic acid injected rats 24 h after intraventricular injection of cycloheximide or saline. Kainic acid $(1 \ \mu g$ in $1 \ \mu l$ of 0.9% NaCl) was infused into dorsal hippocampus. At 6 h later the rats received an intraventricular injection of either cycloheximide (500 μg in $20 \ \mu l$) or saline through a permanently implanted cannula. Rats were killed 24 h after the administration of cycloheximide or saline. $n = 6$.

injection, the increase in ME content peaked during the first 4 days after the injection and returned to control level by 2 weeks (Fig. 1). A small increase in the ME content (30–40%) was also found in the nucleus caudate and septum; in contrast, the ME content in other brain regions remained unchanged. The levels of substance P, γ-aminobutyric acid (GABA) and glutamate did not increase in either side of the hippocampus 3 days after the intrahippocampal injection of KA, suggesting that the enhancement of ME content elicited by such an injection is a specific effect. A selective increase in hippocampal ME content was also elicited by intraseptal, intrastriatal or intraventricular injections of KA (Table 1). As these injections of KA in various brain regions also caused recurrent motor seizures, it became apparent that the recurrent seizures may be related to the mechanism that triggers the increase in hippocampal ME. This hypothesis was strengthened by the finding that the increase in hippocampal ME content was also observed 2 days after the recurrent seizures induced by either isoniazid or by repeated electroconvulsive shocks (four shocks given at 30 min intervals, data not shown). Moreover, the increase in hippocampal ME content elicited by intrahippocampal KA injection was completely blocked by an injection of phenobarbital which prevents the seizure activity induced by intrahippocampal KA (Fig. 2). Muscimol (like phenobarbital) prevented the increase in hippocampal ME content and the convulsions elicited by KA (data not shown). Thus the evidence we have reported supports the view that recurrent seizures may increase the hippocampal ME content.

Table 1 Hippocampal ME content 3 days after intracerebral injections of KA

Route of injection	Dose	Met-enkephalin (ng per mg protein)	
		Control	Treated
Intrastriatal	(1 μg)	0.60 ± 0.04	1.7 ± 0.1*
Intraseptal	(0.5 μg)	0.50 ± 0.03	1.5 ± 0.12*
Intraventricular	(0.25 μg)	0.52 ± 0.03	0.52 ± 0.04
	(0.5 μg)	0.52 ± 0.03	0.60 ± 0.05
	(1.0 μg)	0.52 ± 0.03	1.0 ± 0.07*
	(2.0 μg)	0.52 ± 0.03	1.5 ± 0.12*

The coordinates, according to König and Klippel[5], for the intracerebral injections were: intraseptal (A, 7.8; L, 0; V, 1.0), intrastriatal (A,7.8; L,2.5; V,0) and intraventricular (lateral-ventricle through a permanently inplanted plastic cannula). $n = 6$–10.
 * $P < 0.05$.
Fig. 3   Effect of pretreatment with phenobarbital (50 mg per kg, intraperitoneally) on the kainic acid induced increase in hippocampal Met-enkephalin content. Kainic acid (1 µg in 1 µl of 0.9% NaCl) was infused into dorsal hippocampus of rats under anaesthesia by either ether or equithesin (main components are chloral hydrate and pentobarbital). For the rats pretreated with phenobarbital, ether was used as anaesthetic. Phenobarbital was given 30 min before and 2 h after the injection of kainic acid. $n = 6$; * significantly different from control value, $P < 0.05$.

The mechanism of metabolic regulation of hippocampal ME is still unknown. The biphasic modification of the hippocampal ME content elicited by intrahippocampal injections of KA indicates that the metabolic state of hippocampal ME can change in response to an increase or a decrease in the rates of neuronal activity. A study of the time course of the elevation of the ME content in the hippocampus ipsilateral or contralateral to the KA injection, revealed that the extent of the increase was greater in the contralateral hippocampus but the increase was longer lasting in the ipsilateral hippocampus (Fig. 1). The persistent modification of the ME content in the injected hippocampus suggests that KA may relieve ME neurones from a tonic inhibition by GABA or other inhibitory neurones.

The hippocampus is important in the modulation of aggression[8] and memory[9], and seems to be closely associated with the pathogenesis of epilepsy[10]. This region is particularly prone to convulsions[11]. Stimulation of opioid receptors has an important role in seizures—for instance, microinjection of Leu-enkephalin into the dorsal hippocampus of cats and rats produces epileptiform patterns of electrical activity in the hippocampal EEG. This convulsant action of enkephalin was prevented by microinjection of naloxone[12]. Furthermore, naloxone curtails but morphine exacerbates the postictal behavioural depression, suggesting that opioid peptides are released during the seizure and have a role in the postictal depression of motor activity[13,14]. Although the present study does not make clear the precise mechanism whereby the biphasic change in hippocampal ME content influences seizures, it is clear that the ME content of hippocampus is decreased during recurrent seizures, and these episodes trigger a delayed, long term, rebound increase in the hippocampal ME content.

We thank Mr F. Storch for technical assistance.

Brain noradrenaline depletion prevents ECS-induced enhancement of serotonin- and dopamine-mediated behaviour

A. R. Green

MRC Clinical Pharmacology Unit, Radcliffe Infirmary, Oxford OX2 6HE, UK

J. F. W. Deakin

Division of Neurophysiology and Neuropharmacology, National Institute for Medical Research, Mill Hill, London NW7 1AA, UK

When rats are given a series of electroconvulsive shocks (ECSs) over several days, they display enhanced behavioural responses to both serotonin- and dopamine-receptor agonists [1-3]. Because these changes are seen when the ECS is given in ways closely mimicking the clinical administration of electroconvulsive therapy (ECT), it has been suggested that the changes in postsynaptic monoamine function may be involved in the antidepressant mechanisms of ECT[4,5]. Ligand-binding studies have excluded the possibility that ECS alters the characteristics of either the serotonin or dopamine receptor[6-8]; ECS may therefore be acting on neuronal systems which modulate monoamine neurotransmission. As repeated ECS has recently been reported to decrease both noradrenaline (NA)-sensitive adenylate cyclase[9] and β-adrenoreceptor binding[8,10,11], we have examined here whether changes in NA function are related to the effects of ECS on the serotonin- and dopamine-mediated behaviours. We demonstrate that although selective depletion of NA does not alter the drug-induced serotonin- and dopamine-mediated responses, it abolishes the ECS-induced enhancement of these behaviours.

Rats were anaesthetized with Nembutal (60 mg per kg), and 8 µg of 6-hydroxydopamine (6-OHDA) in 2 µl vehicle was stereotaxically injected bilaterally into the locus coeruleus and dorsal and ventral noradrenergic bundles at a level 2 mm caudal to the substantia nigra. The efficacy and specificity of the lesions were confirmed biochemically (Table 1).

Ten days after operation, sham-operated and lesioned rats were given five ECSs (130 V, 50 Hz sinusoidal for 1 s through earclip electrodes) over 10 days (days 1, 3, 5, 8 and 10). ECS-treated rats were compared with animals (sham-operated and lesioned) which had received anaesthetic only. The behavioural responses of the rats to the putative serotonin agonist quipazine (25 mg per kg) or the dopamine agonist apomorphine (2 mg per kg) were examined 24 h after the final ECS or anaesthetic treatment. These behavioural responses were quantified by placing groups of three animals in cages on Automex activity meters (PMS Instruments).

Quipazine induced several abnormal behaviours[14], and hyperactivity components were recorded by the meters. The lesion did not affect the quipazine response in non-shocked animals (Fig. 1). Furthermore, ECS enhanced the quipazine-

Table 1   Effect of the 6-OHDA lesion on whole brain monoamine concentrations

	Brain monoamine concentration (µg per g brain)		
	Noradrenaline	Dopamine	Serotonin
Sham	0.31 ± 0.01 (14)	1.01 ± 0.10 (14)	0.30 ± 0.01 (18)
Lesioned	0.04 ± 0.02 (14)*	0.85 ± 0.09 (15)†	0.31 ± 0.02 (9)

Results show mean ± s.e.m. with number of observations in parentheses. Different from sham-lesioned control values: * $P < 0.001$; † $P < 0.05$. Brain catecholamines were assayed by the method of Chang[13] and serotonin by the method of Curzon and Green[14].
Fig. 1 Effect of 6-OHDA-induced lesions of brain noradrenergic systems on ECS-induced enhancement of quipazine- and apomorphine-mediated locomotor activity. Responses of the sham-operated (marked S and open columns) and noradrenergic-lesioned rats (marked L and stippled columns) are shown. Locomotor activity in groups of three rats following quipazine (25 mg per kg, intraperitoneally) {left hand side} or apomorphine (2 mg per kg, intraperitoneally) {right hand side} was measured in both sham and lesioned groups (control responses). Other groups were given five ECSs spread over 10 days and tested with the two drugs (ECS responses). Results show responses to both drugs in five or six experiments and are reported as the mean ± s.e.m. of the locomotor counts in the 50 min following drug administration.
* Different from appropriate control response of lesioned animals:
$P < 0.01$.

induced behaviour in the sham-operated rats, as previously reported in unoperated rats[3], but completely failed to alter the hyperactivity response in NA-depleted animals (Fig. 1).

Apomorphine produced a similar locomotor response in both the sham-operated and lesioned rats that had not received ECS (Fig. 1). Following ECF administration there was the expected potentiation of the apomorphine response[1] in the sham-operated animals, but this failed to occur in the lesioned rats (Fig. 1). The degree of enhancement in both serotonin- and dopamine-mediated responses ($\sim$30%) produced by ECS administration was very similar to that seen in other recent experiments in this laboratory[4].

These results demonstrate that destruction of brain noradrenergic systems totally abolishes the ability of ECS to potentiate quipazine- and apomorphine-induced hyperactivity. They also demonstrate that NA is not involved in the mediation of the behavioural syndromes themselves, as the lesion was without effect in non-shocked animals. This result is consistent with the finding that NA depletion with disulfiram did not alter the serotonin-mediated behaviour[15]. Our data suggest that changes occur in brain noradrenergic systems during ECS that result in enhancement of serotonin- and dopamine-mediated behaviour. Several observations indicate that ECS does affect noradrenergic systems: repeated ECS increases tyrosine hydroxylase activity[16], accelerates NA turnover[17,18] and inhibits NA re-uptake at the nerve ending[19,20]. These observations may indicate an increased release of NA from the nerve ending, which could result in the reduction in β-receptor binding observed in ECS-treated rats[8,10,11]. However, this interpretation may be challenged by the finding that ECS decreases the sensitivity of adenylate cyclase to NA in rat forebrain slices, as this occurred in 6-OHDA-lesioned rats[9]. Nevertheless, it is clear that presynaptic NA systems must be involved in the production of the enhanced monoaminergic responses we have observed following ECS. This view is supported by our recent finding that catecholamine synthesis inhibition also abolishes the ability of ECS to enhance serotonin- and dopamine-mediated behaviours[22].

Although the lesion produced a slight (16%) reduction in brain dopamine content (Table 1), this could not explain our findings, first, because apomorphine is an agonist and second, because the DA denervation would, if anything, increase the apomorphine-mediated response, by producing receptor supersensitivity.

These results demonstrate a noradrenergic mechanism of action of ECS in potentiating serotonin- and dopamine-mediated behaviours. It is tempting to speculate that the antidepressant action of ECT may involve similar mechanisms, in view of the many lines of evidence implicating monoamines in the aetiology of depression and in the mechanism of action of antidepressant drugs (reviewed in ref. 21).

Partial denervation in inactive muscle affects innervated and denervated fibres equally

A. Cangiano & L. Lutzemberger

Istituto di Fisiologia, Università di Pisa,
Via S. Zeno, 31, Pisa, Italy

Possible causal factors of denervation-induced changes in muscle include inactivity, products of nerve degeneration and lack of a nerve-borne trophic agent. We now show that if the innervated fibres in a partially denervated rat muscle are rendered inactive, they undergo a reaction as intense as that of the denervated fibres. This provides further support for the view that the effects of denervation on the extrajunctional muscle membrane result from a combination of muscle inactivity and of nerve breakdown products acting diffusely throughout the muscle.

Denervation affects the properties of skeletal muscle fibres through changes which can be attributed in part to inactivity of the muscle[1,2] and in part to factors arising independently of changes in impulse activity[3-9]. Thus denervation elicits larger changes in resistance to tetrodotoxin (TTX) of the muscle action potential[5,8], fibrillatory activity[8,9] and extrajunctional acetylcholine (ACh) receptor density[6,7,9] than muscle paralysis in the absence of nerve degeneration. The difference in efficacy between denervation and paralysis *per se* could arise if cutting the nerve would interrupt the flow of neurotrophic substances to the muscle (for review, see ref. 10). Alternatively, the cut could, by causing nerve degeneration, give rise to pathological factors in the muscle which directly or indirectly affect the muscle fibres.

The latter 'products of nerve degeneration' hypothesis has recently received considerable experimental support[2,11-13]. For example, in partially denervated muscles not only the denervated but also the remaining innervated fibres develop resistance to TTX, although the innervated fibres respond less strongly[12] (but see refs 14, 15). The weaker response of the innervated fibres could be due to their activity since muscle activity is known to inhibit ACh receptor synthesis[16] and other effects of denervation[2]. In the absence of this suppressive effect

Max. rate of rise of spikes

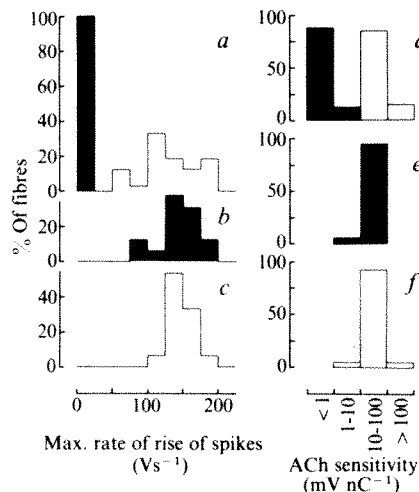
ACh sensitivity
(mV nC⁻¹)


Fig. 1 Resistance of action potentials to tetrodotoxin (a, b, c) and sensitivity to microiontophoretically applied acetylcholine (d, e, f) measured in the same soleus muscle fibres at 1.5–2 mm from the endplate region. Each population is composed of 25–40 fibres from four to five muscles. a And d represent purely impulse-blocked (solid columns) and totally denervated (open columns) muscles. b, c, e And f represent partially denervated muscles (by sectioning the radicular nerve L_5) with an impulse-blocked innervation. Innervated (b and e) and denervated (c and f) fibres were distinguished on the basis of presence or absence of miniature endplate potentials (m.e.p.ps) at the endplate region. The percentage of denervated fibres found in the soleus muscles ranged from 36 to 68%. Resistance to TTX was measured at the endplate region, and, in conjunction with sensitivity to ACh, 1.5–2 mm away from it. Two intracellular micropipettes, one for recording (3 M KCl) and the other for passing currents (2 M K citrate) were used, while a third micropipette was put in a just extracellular position for ACh iontophoresis (3 M AChCl). Each fibre was followed over the indicated distance by shifting the recording electrode while applying hyperpolarizing pulses with the current electrode. An alternate pattern of exploration was followed, so that in one fibre the extrajunctional measurements were done first and those at the endplate region second, whereas in the next fibre the reverse order was followed. Resistance to TTX was determined eliciting and recording action potentials in the presence of TTX 10^{-6} M (refs 12, 24). The resting membrane potential was set at −100 mV and the strength of the depolarizing pulse adjusted to give a constant delay of 4 ms between its onset and that of the action potential. The amount of TTX resistance was measured as the maximal rate of rise of the action potential given by its electronically recorded first derivative through an RC circuit (× 10^5 Ω, 100 pF). Sensitivity to ACh was measured with conventional techniques[25]. The ACh pipettes were several hundred megohms in resistance and required less than 2 nA braking current. The RMP was set at a constant value of −80 mV with the current electrode while evoking an ACh potential. Units of ACh sensitivity represent millivolts of depolarization per 10^{-9} C of charge passed through the iontophoretic pipette. The oxygenated mammalian Ringer's solution bathing the muscles was kept at a temperature of 28 °C. The results obtained for the TTX resistance at the endplate region were similar to those shown in this figure, although all values were moderately higher than in the extrajunctional region, confirming that after denervation TTX resistance develops earlier near the endplates[24]. Thus, the maximal rate of rise of spikes in the partially denervated muscles was 128 ± 5.4 Vs⁻¹ (±s.e.m.) for the denervated fibres and 127 ± 6.7 for the innervated fibres as compared to 3.1 ± 1.5 for the paralysed control muscles with intact nerves. As far as the EDL muscles are concerned, the results obtained in three impulse-blocked, partially denervated muscles examined between 56 and 72h were similar. For example, the maximal rate of rise in TTX 10^{-6} M at the endplate region was 108 ± 10.3 for 16 denervated fibres and 122 ± 6.9 for 22 innervated fibres, while in the paralysed control muscles with intact nerves the average value was only 11 ± 2.1 (24 fibres). At the time of the acute experiment stimulation of the sciatic nerve proximal to the cuff evoked no contraction of EDL and soleus muscles in partially denervated or control preparations with intact nerves. Stimulation distal to the cuff evoked muscle twitches and transmitted action potentials could be recorded from the muscle fibres before TTX was added to the perfusion fluid. Frequency of m.e.p.ps was normal (2.3 ± 0.1 s⁻¹ in 31 innervated fibres of four partially denervated soleus and 2.1 ± 0.1 s⁻¹ in 29 fibres of three normal soleus).

of activity, the muscle fibres may become particularly sensitive to the effects of degeneration of the nerve. It is therefore possible that these effects may combine with the effects of inactivity to produce the full response to denervation. In that case one would expect innervated but inactive fibres to respond as strongly as adjacent denervated fibres to extensive partial denervation. We have tested this possibility by partially denervating muscles which in addition were paralysed by a chronic conduction block in the nerve.

The extensor digitorum longus (EDL) and the soleus muscles of adult rats were chronically inactivated by blocking impulse conduction in the sciatic nerve with TTX-impregnated cuffs[6]. At the same time the muscles were partially denervated by cutting the radicular nerve L_5 just outside the vertebral canal. Control muscles were either completely denervated or subjected to chronic nerve conduction block only. Soleus and EDL muscles were examined 56–72 h later *in vitro* for the development of extrajunctional sensitivity to ACh and of junctional and extrajunctional resistance to TTX, all essentially absent in normal soleus and EDL muscles[15,17]. The denervated control muscles were then already highly resistant to TTX and sensitive to ACh (Fig. 1a, d, open columns) while the paralysed control muscles with intact nerves were just beginning to respond (Fig. 1a, d, solid columns). As expected, the denervated fibres in the partially denervated muscles had values comparable to those in the denervated control muscles (Fig. 1c, f). The innervated fibres, on the other hand, were as resistant to TTX and as sensitive to ACh as the denervated fibres (Fig. 1b, e), which was much more than expected from the inactivity alone (Fig. 1a, d, solid columns).

Note that the fibres in the muscles with only about 50% denervation respond as strongly as the fibres in the totally denervated muscles (Fig. 1). This illustrates the efficacy of the effect of partial denervation and one possible explanation would be that at this relatively late time the muscle fibres are already responding maximally. We therefore examined the responses at an earlier time, using muscles in which we had produced different degrees of partial denervation (~10% to 90%) (Fig. 2). The results show that at 50 h there was a positive correlation between the percentage of denervated fibres and resistance to TTX for both innervated and denervated fibres (Fig. 2). Furthermore, for any degree of partial denervation there was essentially no difference between denervated and innervated fibres. Consequently, in inactive muscles, innervated and denervated fibres give equal responses to partial denerva-

% Of denervated fibres
Fig. 2 TTX resistance measured in denervated (●) and innervated impulse-blocked (○) fibres, plotted as a function of the percentage of denervated fibres found in each partially denervated soleus muscle. Each point represents the average TTX resistance measured at 50 h near the endplate region in 4–15 fibres per muscle (the lowest figure applies either to the denervated or the innervated fibres of those muscles exhibiting the lowest or the highest percentage of denervation respectively). Totally denervated (▲) and purely paralysed (□) muscles are also shown for comparison. The lowest percentages of denervation were obtained by incompletely sectioning the radicular nerve L_5. To obtain a reliable value for the percentage of denervated fibres, 40–50 fibres were recorded in each muscle to observe the presence or absence of m.e.p.ps. Bars represent the standard error of the mean.
Fig. 3 Class distribution of TTX resistance measured near the endplate region in innervated impulse-blocked fibres (a) and denervated fibres (b) of 'closely' (columns with continuous lines) and 'distantly' (columns with broken lines) partially denervated soleus muscles at 50 h (about 30 fibres measured per muscle). The percentage of denervated fibres found in the muscles of the two populations was comparable: average 40% for the closely denervated (5 muscles) and 53% for the distantly denervated muscles (8 muscles). The difference in the length of the 'nerve stump' for the two populations was about 6 cm. Although no obvious trauma of the soleus occurred with 'close' partial denervation since the muscle was not exposed the possibility was considered that the greater TTX resistance at 50 h was not a nerve-length effect but a result of muscle damage, particularly because inactive muscles should be more responsive. However, this possibility was excluded because no TTX resistance was observed in the impulse-blocked soleus of three rats in which the attempted close section of the soleus nerve had failed to damage any motor axon.

tion as expected if nerve degeneration causes substances to appear in the interstitium which change the membrane properties of all fibres in that region.

The objection might be raised that nerve degeneration in the periphery is not the only consequence of partial denervation. Axotomy might have central effects which might affect the production of neurotrophic substances in adjacent intact motoneurones. In the frog, for instance, nerve section results in sprouting from contralateral intact axons apparently through changes taking place in the spinal cord[18]. To examine this possibility we partially cut the nerve supply either far from the soleus muscle by sectioning (as before) the radicular nerve L_5 or close to the muscle by incompletely sectioning the soleus nerve. The innervated fibres were rendered inactive by a TTX-containing cuff around the sciatic nerve. In agreement with previous results obtained in totally denervated muscles[4], after 50 h the TTX resistance of the denervated fibres was significantly higher in muscles with a short nerve stump than with a long nerve stump (Fig. 3b). Identical behaviour was observed in the innervated fibres of the same muscles (Fig. 3a), which indicates that the effect on the innervated fibres, as that on the denervated, is peripheral in origin and probably related to the fact that short nerve stumps degenerate more quickly than long nerve stumps[19]. Had the effect of partial denervation on the innervated fibres been of central origin, their response would have been expected to lag behind that of the denervated fibres, and to occur earlier in the experiments where the nerve was cut close to the spinal cord.

Thus the present results confirm and extend our previous study[12] by showing that partial denervation also affects the innervated fibres within the muscle. In muscles where the suppressive influence of activity on ACh receptor synthesis and other denervation-like changes[2,16] has been removed, the responses of innervated and denervated fibres become indistinguishable. This suggests that the response of the muscle fibre membrane to denervation may be accounted for as the combined result of inactivity and the effects of nerve degenera-

tion *per se*. The effect could be due to nerve breakdown products acting either directly on the muscle fibres or indirectly via Schwann cells, cells of the immune system or other tissue cells. It should be emphasized that in this work only the effects on the extrajunctional membrane have been studied and that the properties of the postjunctional membrane may be controlled by different mechanisms[20-23].

Proteinase inhibitors suppress the development of experimental allergic encephalomyelitis

Celia F. Brosnan*, Wendy Cammer†,
William T. Norton† & Barry R. Bloom‡

Department of Pathology*, Neurology† and Neuroscience‡. Microbiology and Immunology, and Cell Biology, Albert Einstein College of Medicine, 1300 Morris Park Avenue, Bronx, New York 10461

Experimental allergic encephalomyelitis (EAE) is an autoimmune inflammatory disease of the central nervous system (CNS) induced in animals by sensitization with white matter or with myelin basic protein (BP)[1,2]. EAE is dependent on cell-mediated immune (CMI) reactions requiring T-cell sensitization[2-4], and demyelination is observed in the vicinity of perivascular infiltrates of mononuclear cells[5]. However, the mechanisms by which CMI reactions initiate the clinical and pathological expression of EAE have not been well defined. Numerous mechanisms have been proposed for the degradation of myelin, including activated components of the complement system[6,7] and the action of enzymes released by inflammatory cells[8,9]. Among these enzymes, lipases, lysosomal acid proteinases and lymphocyte proteinases have been stressed[8-14]. Recent reports from this laboratory have suggested that damage to the myelin sheath may be initiated by the release of neutral proteinases, including plasminogen activator, from macrophages activated during an immune response[15]. If neutral proteinases and, particularly, plasmin, generated from plasminogen by plasminogen activator, have a key role in initiating the clinical signs and pathology of the demyelinating diseases, it might be expected that inhibitors of these enzymes would protect sensitized animals against EAE. Here we have shown that aminomethylcyclohexane carboxylic acid (AMCA), ε-amino-caproic acid (EACA) and p-nitrophenylguanidinobenzoate (NPGB), which are inhibitors of plasminogen activator and other neutral proteinases, gave significant protection against the clinical expression of EAE in Lewis rats. Other protease inhibitors gave partial or no protection.

Fig. 1 Weight loss curves for two experiments. Animals were sensitized and drugs administered as described in Table 1 legend. The mean weight for each group is expressed as per cent of the mean weight of the respective group at day 7.

inhibitors of microbial origin[17], did not prevent paralysis at a dose of 1 mg twice a day, and insufficient material was available for testing at higher doses.

AMCA is 5–10 times more effective than EACA as an inhibitor of fibrinolysis[18,19], and consistent with this is the finding that AMCA was more effective than EACA in protecting against EAE (Table 1). However, interpretation of the clinical data for NPGB, pepstatin and Trasylol is more complicated. NPGB, which also inhibits plasminogen activator and plasmin, becomes toxic at approximately 10 mg per day, is difficult to solubilize and hydrolyses readily. We suspect that the beneficial effects of NPGB in inhibiting EAE are offset by toxic effects of the hydrolysis product, p-nitrophenol[20]. Of the inhibitors used, AMCA and NPGB were most effective in decreasing the extent of weight loss which is characteristic of EAE (Fig. 1).

Pepstatin was also difficult to solubilize, and initially it was administered as a suspension in 10% ethanol. In these experiments, six out of nine animals failed to become paralysed. In the experiment shown in Fig. 1, pepstatin protected against weight loss, but this effect was not consistent. To control for the possibility that either the alcohol solvent or the particulate nature of the polypeptide, pepstatin, was protective, we treated rats with a suspension of polyvaline in 10% ethanol. Polyvaline, which is not known to inhibit proteinases, did not protect against EAE (Table 1). In animals treated with Trasylol, the onset of clinical signs was earlier and paralysis more severe than in the control animals (Table 1), and the animals lost more weight than the controls (Fig. 1).

The degree of infiltration of the CNS by inflammatory cells was evaluated histologically. Routine haematoxylin and eosin staining showed some pathological evidence of disease in animals from all the groups, but in animals successfully treated with pepstatin and NPGB (Fig. 2), both perivascular infiltration and sub-meningeal inflammation were markedly reduced. In asymptomatic animals treated with the antifibrinolytic drugs AMCA and EACA, haematoxylin and eosin sections showed perivascular infiltration to be reduced only slightly; however, it was obvious from toluidine blue-stained sections of AMCA-treated animals that the extent of invasion into the white matter and the degree of demyelination in the vicinity of the inflammatory cells were reduced considerably (Fig. 3). Histological examination of paralysed animals receiving Trasylol demonstrated a widespread diffuse cellular invasion at all levels of the spinal cord and brain, and the degrees of infiltration and demyelination were more severe than in paralysed control animals.

The findings that Trasylol exacerbated EAE and that pepstatin, an inhibitor of acid proteinases, conferred partial protection against EAE, would seem to be inconsistent with our hypothesis. Two modes of action for pepstatin can be considered. One is that

Male inbred Lewis rats weighing ~300 g were injected on day 0 in each hind footpad with 0.1 ml of an emulsion containing a freshly prepared 50% suspension in saline of guinea pig spinal cord in an equal volume of complete Freund's adjuvant containing 10 mg ml⁻¹ of heat-killed *Mycobacterium tuberculosis*, H 37 RA. Starting on day 6, proteinase inhibitors were injected intraperitoneally twice daily, and sensitized control animals were injected with sterile non-pyrogenic saline. Thereafter, rats were weighed daily and scored for clinical expression of EAE. Control animals consistently became ill on days 12–14. On day 16, animals were anaesthetized with Nembutal, killed and prepared for histology by whole body perfusion with formaldehyde for haematoxylin and eosin staining, or with glutaraldehyde for epon embedding and staining with toluidine blue[16].

Table 1 shows the proteinase targets of the respective inhibitors and summarizes the results for prevention of paralysis and pathology in the sensitized animals. AMCA was the most effective agent; EACA, NPGB and pepstatin consistently protected some of the animals. Leupeptin and antipain, which are proteinase

Table 1 Protection of sensitized rats from EAE by injection of proteinase inhibitors

Drug	Proteinase(s) vulnerable to drug *in vitro*	Daily dosage	Perivascular infiltration (spinal cord)	Clinical grade	Effect on EAE rats paralysed/total
Controls			2.9	4.0	30/35
AMCA	Neutral proteinases, incl. Plg A and plasmin[18,19]	100 mg	2.3	0.46	2/16
EACA	Neutral proteinases, incl. Plg A and plasmin[18,19]	1.6 g	2.0	1.8	4/10
NPGB	Plasmin; Plg A; trypsin; thrombin[20,34]	2 mg	1.6	1.6	7/22
Pepstatin	Acid proteinases; cathepsin D[17]	2 mg	1.5	1.5	3/9
Leupeptin	Neutral proteinases; cathepsins A and B[17]	2 mg	3.0	3.7	7/8
Antipain	Neutral proteinases; cathepsins A and B[17]	2 mg	2.5	2.2	3/5
Trasylol	Neutral proteinases[18,19]	4,000 units	3.2	4.5	9/10*
Polyvaline	None; control for pepstatin	2 mg	3.0	4.0	5/5

EACA, AMCA (both Sigma), leupeptin, antipain and Trasylol (Bayer) were administered in sterile non-pyrogenic saline, NPGB (ICN Nutritional) was administered in 1% dimethyl sulphoxide (DMSO) in saline or in 10 mM sodium acetate buffer, pH 3.6, in saline and pepstatin (Bristol Laboratories) and polyvaline (ICN Nutritional) were administered as suspensions in 10% ethyl alcohol in saline. Beginning on day 7 after sensitization, rats in the experimental groups were injected with inhibitors twice daily, and rats in the control groups were injected with saline twice daily. We also tested pepstatin in 2% DMSO. No protection was observed, but because the control animals tested with 2% DMSO alone showed marked exacerbation of the disease, the results are not included here. Clinical grades on a scale of 1–6 were evaluated by three independent investigators according to the protocol of McFarlin, Blank and Kibler[35]; and perivascular infiltration was graded on coded slides using an arbitrary scale of 1–4. Abbreviations used: Plg A, plasminogen activator; EAE, experimental allergic encephalomyelitis; AMCA, transaminomethylcyclohexane carboxylic acid; EACA, ε-aminocaproic acid; NPGB, p-nitrophenylguanidobenzoate.

* Rats became paralysed 2 days before controls.

acid proteinases, which can be secreted by macrophages[21], may be involved in the clinical and pathological expression of EAE[9-14]. Alternatively, pepstatin in suspension might be toxic for phagocytic cells. Although we cannot rule out either of these possibilities, the histological data for NPGB and pepstatin suggest that these drugs may act at stages in the activation of the cell-mediated immune system before the entry of macrophages into the CNS.

The histological picture for AMCA, where the infiltrating mononuclear cells characteristic of EAE were found but demyelination was not observed (Fig. 3), strongly suggests that AMCA protects against demyelination by inhibiting plasminogen activator, plasmin or other neutral proteinases after macrophage infiltration of the white matter.

AMCA and EACA have had limited clinical application in recent years in treating subarachnoid haemorrhage, angioneurotic oedema and chronic urticaria, with absent or moderate side effects[22-29].

Of the series of proteinase inhibitors used in the present studies on EAE, the partial efficacies of pepstatin, NPGB and EACA are consistent with the results of other investigators[30-33]. The degree of protection obtained with NPGB gives further credence to the role of serine proteinases in EAE, especially if one takes into consideration the toxicity of NPGB. The results obtained with Trasylol (aprotinin) are disturbing and difficult to explain but have been independently observed by Smith[33]. It will be possible to speculate on the mechanisms involved when more data become available regarding the effects of Trasylol on circulating and tissue levels of neutral proteinases, particularly plasmin and plasminogen activator. The results suggest caution in the possible use of any of these drugs in humans. The most significant observation is the marked protective effect of the antifibrinolytic agent, AMCA. In animals treated with AMCA the histological evidence of inhibition of demyelination in the vicinity of infiltrating mononuclear cells supports the hypothetical participation of the macrophage-secreted plasminogen activator in the pathogenesis of EAE, and, possibly, in other inflammatory demyelinating conditions.

Myasthenia gravis induced by monoclonal antibodies to acetylcholine receptors

Vanda A. Lennon & Edward H. Lambert

Departments of Immunology, Neurology and Physiology, Mayo Clinic and Medical School, Rochester, Minnesota 55901

Autoantibodies to nicotinic acetylcholine receptors (AChRs) are demonstrable in sera of approximately 90% of patients with myasthenia gravis (MG), a disease of neuromuscular transmission[1]. The consistent abnormality in MG is a low amplitude of miniature endplate potentials (m.e.p.ps) due to decreased sensitivity of the postsynaptic membrane to the neurotransmitter, acetylcholine (ACh). This reflects a decrease in numbers of AChRs in the membrane (for review see ref. 2). The pathogenicity of anti-AChR antibodies has been documented *in vivo* by passive transfer of MG from human to mouse[3] and from rat to rat[4] and *in vitro* on cultured muscle cells[5-8]. However, titres of anti-AChR antibodies in serum do not correlate closely with severity of muscle weakness in MG patients[1]. This lack of correlation very probably reflects the heterogeneity of specificities of anti-AChR antibodies which is known to exist in MG[2]. For example, antibodies directed to determinants of AChRs which are inaccessible *in vivo* may be generated in the course of the disease without being relevant to disease pathogenesis. Identification of antigenic determinants of AChRs which are the primary target(s) of antibody attack in MG is a logical prerequisite to designing antigen-specific immunotherapy for this disease. We report here the production by hybridoma cells of monoclonal rat antibodies reactive with muscle AChR, both adult and fetal, in all of six mammalian species studied. Antibodies produced by two of these hybridoma lines bound to one or more antigenic determinant(s) exposed extracellularly, but remote from the binding site for cholinergic ligands, in the postsynaptic membrane of muscle, and caused a defect of neuromuscular transmission in mice, rats and guinea pigs. These findings establish conclusively that neuromuscular transmission can be impaired by monospecific anti-AChR antibodies which do not inhibit the binding of neurotransmitter to its receptor site.

Cells of a mutant mouse myeloma line, S194/5.XXO.BU.1, resistant to 1×10^{-4} M bromodeoxyuridine (BUdR), and a non-producer of immunoglobulin were maintained in Dulbecco's modification of Eagle's medium supplemented with 10% fetal calf serum; BUdR (1×10^{-4} M) was present for 72 h preceding fusion. AChR-primed lymphocytes were obtained from female Lewis rats inoculated at approximately monthly intervals with

AChR (purified from the electric organ of *Torpedo californica* by affinity chromatography on α-neurotoxin of *Naja naja siamensis* venom) with adjuvants[9]. At 4–5 days after final challenge with AChR, 10^8 lymphocytes from regional lymph nodes were mixed with 10^7 myeloma cells for fusion in 43% (vol/vol) polyethylene glycol 1500 (BDH) as described by Galfre *et al.*[10]. Cells were dispensed (2×10^6 lymphocytes per 2.0-ml well) in selective hypoxanthine/ aminopterin/thymidine HAT medium, with 2-mercaptoethanol, 1×10^{-4} M, into multi-well dishes (Costar no. 3524) seeded 1 day previously with rat peritoneal cells[11]. Hybrid cells producing antibodies of interest were cloned by limiting dilution in micro-well plates (0.4 cells per 0.2-ml well). To ensure monoclonality, each clone selected for study was isolated from a second cloning at this low density. Hybridomas secreting antibodies to AChR were identified by an immunoprecipitation radioimmunoassay[4] using solubilized AChR complexed with an excess of ^{125}I-α-bungarotoxin (α-BT), a cholinergic ligand which binds essentially irreversibly to the receptor's binding site for ACh. Nonspecific binding of α-BT or AChR (c.p.m. precipitated in non-immune serum) was subtracted.

Fusion of a non-secreting mouse myeloma with lymph node cells from rats primed in optimal conditions (5 days after a secondary or tertiary intradermal challenge by AChR) yielded reproducibly a high frequency of hybridomas; in five experiments, hybridoma cells appeared on initial plating in a mean of 73% of the wells; all these produced antibodies reactive with *Torpedo* AChR. In individual fusion experiments 26–100% of the hybridomas recognized determinants of *Torpedo* AChR which were shared by AChR of mammalian skeletal muscle.

The three cloned lines studied in detail here have been passaged continuously for 11–15 months without loss of specific antibody production. Their patterns of reactivity with AChR from a variety of sources are shown in Table 1. McAb-1 recognizes a determinant unique to *Torpedo*; McAb-2 and McAb-3 recognize determinants common to AChR of *Torpedo* and adult and fetal skeletal muscle from all of six mammalian species tested. Variation in the degree of binding to AChR of separate species (and to fetal and adult AChR of dog and cat) suggests differences in conformation, accessibilty and perhaps numbers of individual determinants on AChR solubilized in non-ionic detergent from membranes of muscle from different sources. To determine whether a monoclonal antibody might bind to antigenic determinants exposed extracellularly in innervated mammalian muscle *in vivo*, athymic male BALB/c nude (nu/nu) mice (ARS Sprague–Dawley), about 7 weeks old, were injected intraperitoneally with $0.2-1.0 \times 10^8$ living hybridoma cells. Mice injected with hybridomas secreting McAb-2 and McAb-3 showed no signs of weakness, weight loss or tumour in 46 days of observation. However, microelectrode studies of forearm and diaphragm muscles[12], carried out between days 7 and 46, revealed a highly significant ($\approx 50\%$) reduction in

Table 1 Specificities of three monoclonal antibodies: comparison of binding to AChRs of different species

Hybridoma Clone	Torpedo*	Relative AChR binding in % of Torpedo AChR bound										
		Rat		Human		Guinea Pig		Dog		Cat		Mouse
		A	F	A	F	A	F	A	F	A	F	A
McAb-1	100	0	0	0	0	0	0	0	0	0	0	0
McAb-2	100	57	56	40	38	15	19	34	14	36	13	39
McAb-3	100	71	69	45	48	24	19	52	22	51	20	49

Several precautions were taken to ensure valid comparison of binding specificities of the monoclonal antibodies. First, affinity-purified *Torpedo* AChR was used as a reference antigen. Preliminary assay was carried out to ensure that dilutions of antibody selected bound approximately 50% of *Torpedo* AChR (that is, in the linear range of binding). Binding of mammalian AChR was then expressed as per cent of the binding of *Torpedo*. To ensure that in each assay the same constant excess amount of mammalian muscle AChR was added, aliquots of each muscle extract were assayed for their AChR content using an excess of a polyspecific rat anti-AChR antiserum. All assays were carried out simultaneously in duplicate with a single batch of reagents. AChR was extracted in 2% Triton X-100 buffer[15]. Only in the case of *Torpedo* was AChR purified (by affinity chromatography on α-neurotoxin agarose). Adult muscle (A) was obtained from limbs of human (amputations), guinea pig, dog and cat, and from eviscerated carcasses of rat and mouse. Fetal muscle (F) was obtained from limbs of human (spontaneous abortions at 23 and 24 weeks gestation), dog (near term), cat (near term) and carcasses of fetal rat (19 d) and guinea pig (8 cm). Although the fetuses selected were at comparable stages of maturation, there is no evidence from species other than rat[22,23] that antigenic differences exist between forms of AChR found in fetal and mature adult muscle.
* Two factors may account for the consistently greater binding to *Torpedo* AChR by McAb-2 and McAb-3: first because *Torpedo* AChR was purified, its antigenic sites would be more accessible for binding; second, solubilized *Torpedo* AChR exists in a predominantly dimer form[24], in contrast to the exclusively monomeric form of mammalian muscle AChR.

Table 2 Pathogenicity of anti-AChR antibodies secreted by clonal hybridomas in nude mice

| Cells inoculated | m.e.p.p. amplitude* | | Serum antibody† titre ($\times 10^{-9}$ M ±s.e.m.) | Muscle AChR‡ | |
	Forearm (mV ± s.e.m.)	Diaphragm (mV ± s.e.m.)		Total content ($\times 10^{-11}$ moles per mouse, ± s.e.m.)	% Complexed with immunoglobulin ± s.e.m.
Nil	0.79 ± 0.042 (7)	1.41 ± 0.107 (7)	0.0 (11)	1.39 ± 0.060 (9)	0
McAb-1	0.73 ± 0.083 (6)	—	0.0 (6)	1.47 ± 0.050 (12)	0
McAb-2	0.38 ± 0.086 (4)§	0.70 ± 0.109 (4)§	8.7 ± 2.77 (4)	0.93 ± 0.143 (8)	52 ± 10
McAb-3	0.39 ± 0.027 (6)§	0.63 ± 0.086 (6)§	227.4 ± 130.51 (6)	0.49 ± 0.032 (6)	86 ± 4

* Microelectrode studies were done as described elsewhere[12]. m.e.p.p. amplitudes were corrected for non-linearity of the endplate response to ACh and to a resting potential of − 75 mV. m.e.p.p. with rise time of 0.6 ms or less were measured at 31 °C. Difference in m.e.p.p. amplitude between forearm and diaphragm is related to smaller diameter of muscle fibres in diaphragm. Diaphragms from mice inoculated with McAb-1 cells were not tested because of adherent tumour cells which were not present in McAb-2 and McAb-3. Numbers in parentheses are number of mice.

† Sera were obtained on days 31–46 and 7–27, respectively, after intraperitoneal inoculation with McAb-2 and McAb-3 hybridomas. Mouse muscle AChR, solubilized in Triton X-100 and complexed with an excess of ^{125}I-α-BT, was used as antigen[15]. Sera from mice bearing McAb-1 hybridoma cells (obtained on days 12–18) had no detectable antibody reactive with mouse muscle AChR, but titres of antibody reactive with *Torpedo* AChR were extremely high (mean 4,000 ± 289 × 10[−9] M), reflecting the prolific intra-abdominal growth of the McAb-1 hybridoma. Binding of *Torpedo* AChR by sera of mice bearing McAb-2 and McAb-3 was similar to their binding of mouse muscle AChR (mean titres for *Torpedo* AChR, 12.0 ± 2.93 × 10[−9] M and 247.7 ± 148.05 × 10[−9] M, respectively).

‡ AChR was extracted in 2% Triton X-100 buffer from homogenized carcasses of individual mice and labelled with an excess of ^{125}I-α-BT. Total AChR and % complexed *in situ* with antibody were determined by immunoprecipitation[15]. Reductions in AChR content of McAb-2 and McAb-3 carcasses are highly significant ($P < 0.01$ and < 0.001, respectively).

§ Significantly different from non-inoculated group (Student's *t*-test, $P < 0.001$). Forearm m.e.p.p. amplitudes are also significantly different from those of McAb-1 group ($P = 0.02$ and < 0.01 for McAb-2 and McAb-3 groups, respectively). McAb-1 is not significantly different from control ($P = 0.5$).

Table 3 Pathogenicity of monoclonal anti-AChR antibodies passively transferred into rats and guinea pigs

| Immunoglobulin injected* | Incidence of muscle weakness | m.e.p.p. amplitude† | | Serum titre of antibody to homologous muscle‡ AChR ($\times 10^{-9}$ M ±s.e.m.) | Muscle AChR§ | |
		Forearm (mV ± s.e.m.)	Diaphragm (mV ± s.e.m.)		Total carcass ($\times 10^{-11}$ moles ± s.e.m.)	% Complexed with immunoglobulin ± s.e.m.
Rats						
Control	0/10	0.63 ± 0.021 (6)	0.89 ± 0.059 (4)	0.0	4.22 ± 0.342 (10)	0
McAb-1	0/2	—	1.05; 0.67	0.0	4.66; 4.10	0
McAb-2	10/10	—	0.36 ± 0.100 (4)	2.9 ± 0.27 (8)	1.67 ± 0.192 (8)	35 ± 1.4 (8)
McAb-3	8/8	0.10 ± 0.018 (7)	0.31 ± 0.067 (4)	11.3 ± 1.54 (8)	1.23 ± 0.103 (8)	50 ± 2.8 (8)
Guinea pigs					Forearm (moles per g × 10[−13])	
Nil	0/3	0.80 ± 0.061 (3)	—	0.0	5.68 ± 0.324 (3)	0
McAb-3	2/2	0.38; 0.25	—	0.21; 0.63	1.56; 1.59	11; 37

* McAb-1, -2 and -3 immunoglobulins were purified from growth medium of hybridoma clones by affinity chromotography on agarose-conjugated goat anti-rat immunoglobulin[18]. Female Lewis rats and adult male guinea pigs were injected intravenously with immunoglobulin (1×10^{-10} moles in each rat and 8×10^{-10} moles in each guinea pig) and killed 2–3 days later. Control immunoglobulin was precipitated by 40% saturated ammonium sulphate from pooled serum of rats inoculated with adjuvants only, and 100 μg was injected into each rat.

† m.e.p.p. amplitudes were measured as described in Table 2 legend. McAb-2 and McAb-3 are significantly different from control ($P < 0.005$ and $P < 0.001$, respectively).

‡ Titre of antibodies in rat and guinea pig serum was determined as described in Table 2 legend but using rat and guinea pig muscle AChR, respectively. Titres of antibodies reactive with *Torpedo* AChR in sera of rats injected with McAb-1 were 4.7 and 8.2 × 10[−9] M.

§ AChR content of muscle was measured as described in Table 2 legend. Values for McAb-2 and McAb-3 rats were significantly lower than for the control group ($P < 0.01$ and < 0.001, respectively).

amplitude of m.e.p.ps in both muscles when compared with the age-matched, non-inoculated mice (Table 2). Furthermore, McAb-2 and McAb-3 antibodies were bound extensively to AChRs of skeletal muscle in the mice and the total amount of AChRs in the muscle was reduced. These three abnormalities are characteristic of MG occurring spontaneously in humans[13] and dogs[14] and in experimental autoimmune MG (EAMG) induced by active immunization with purified AChRs in rats[15] and in mice[16]. Failure of the mice to develop weakness reflects their large safety factor of neuromuscular transmission. Although the reduction in m.e.p.p. amplitude of 50% is highly significant, it is not sufficient to cause clinical signs of weakness in mice or rats[12]. The hybridoma line secreting McAb-1 was tumorigenic in nude mice, and sera of those mice had very high titres of antibodies reactive with *Torpedo* AChR (mean = 4,000 ± 289 × 10[−9] M). However, the immunoglobulin, which recognized only *Torpedo* AChR *in vitro*, did not bind to muscle AChR in the mice and m.e.p.p. amplitudes did not differ significantly from those of age-matched normal nude mice.

To demonstrate that the hybridomas were producing true autoantibodies, McAb-2 and McAb-3 cells (1.4 and 3.5 × 10[8] cells) were injected intraperitoneally into 10-week-old female Lewis rats. Within 24 h profound muscle weakness occurred and

electromyographic abnormalities characteristic of the acute phase of EAMG[12] were demonstrated.

Because of the similar patterns of binding of McAb-2 and McAb-3 to AChR from different sources (Table 1), and because these hybridomas arose from a single fusion experiment, the possibility that they might be identical molecules was examined by isoelectric focusing on polyacrylamide gels using a pH 3–10 gradient[17]. Antibodies were isolated from growth medium by adsorption to agarose-bound goat anti-rat Ig[18], from which they were eluted in 1.0 M propionic acid. After adjustment to neutral pH and dialysis against phosphate-buffered saline, pH 7.4, and 0.02% NaN₃, purified McAb-2 and McAb-3 antibodies bound respectively, 1.09 and 4.37 × 10[−9] moles of solubilized mouse muscle AChR per mg and 3.11 and 7.24 × 10[−9] moles of purified *Torpedo* AChR per mg. Unreduced, the antibodies had very similar isoelectric points (in the range of pH 7.4–7.5). However, reduction by β-mercaptoethanol revealed that the light chain bands of McAb-2 and McAb-3 (confirmed by electrophoresis in a second dimension in a SDS-polyacrylamide slab gel) were distinctly different (p*I* values 7.2 and 6.6, respectively). This indicates that McAb-2 and McAb-3 are different molecules.

Passive transfer of purified McAb-2 and McAb-3 into rats and guinea pigs induced clinical, electrophysiological and bioche-

mical evidence of EAMG (Table 3). Thus, the determinant(s) of AChR recognized by McAb-2 and McAb-3 are exposed extracellularly at the neuromuscular junction in at least three mammalian species (mouse, rat and guinea pig) and are common to all mammalian muscle AChRs examined, including man (Table 1). The fact that both antibodies bound *in vitro* to AChR complexed with ^{125}I-α-BT (molecular weight $\sim$ 8,000) indicates that the antigenic determinant(s) recognized by these antibodies reside outside the receptor's binding site for ACh. Thus, using monoclonal antibodies produced by interspecies hybridomas we have established unequivocally that an autoimmune response to an antigenic determinant located outside the AChR's binding site for the neurotransmitter ACh can cause impairment of neuromuscular transmission *in vivo*. Idiotypic analysis may determine whether the same antigenic determinant of AChR is defined by these two different monoclonal antibodies. Analysis of the idiotypes of monoclonal anti-AChR autoantibodies should provide a means of defining antigenic determinants of AChR relevant to the pathogenesis and suppression of MG.

Two recent reports describe production of hybridomas secreting antibodies to AChR with specificities demonstrated only for *Torpedo* AChR[19,20]. We believe ours to be the first report of the production of autoantibodies by hybridomas. The hybridoma technique will have important applications in the investigation of a variety of human autoimmune diseases, particularly for obtaining pathogenic antibodies of specificities which may not be detectable in serum because of quantitative absorption to target cells[21]. Hybridization of human B lymphocytes with appropriate myelomas should enable direct investigation of those specificities.

We thank Jean Chen, Cindy Uhl, Renee McGovern and Millie Thompson for technical assistance. This work was supported by a grant from the National Institutes of Neurological and Communicative Diseases and Stroke (NS 15057) and a Research Center Grant from the Muscular Dystrophy Association.

Note added in proof: Since this article was submitted for publication it has been reported that murine myelomas hybridized with spleen cells from spontaneously autoimmune mice produced monoclonal anti-RNA[25] and anti-DNA[26] autoantibodies.

Dopaminergic activation of reticulata neurones in the substantia nigra

André Ruffieux & Wolfram Schultz*

Institut de Physiologie, Université de Fribourg, Bd Pérolles, CH-1700 Fribourg, Switzerland

Dendritic release of dopamine (DA) in substantia nigra (SN) is well established in various experimental situations[1-3]. Morphological substrates for DA storage exist in dendrites[4,5], as do dendro-dendritic[6] and dendro-axonic[7] contacts. DA receptors in SN are located on both cells[8] and striato-nigral terminals[9,10]. DA is thought to regulate the activity of neighbouring dopaminergic neurones through its dendritic release by a local feedback mechanism[11,12]. However, dendrites of DA neurones also ramify close to the neuropil of non-dopaminergic reticulata neurones in SN. The question has arisen whether dendritically released DA might also influence these neurones which, to a large extent, project to ventromedial thalamus (VM) and superior colliculus[13]. A necessary condition would be that they are sensitive to DA. In the experiments reported here this was found to be the case—a considerable proportion of nigro-thalamic neurones were activated by iontophoretically applied DA. This contrasts with its known depressant effect on pars compacta DA neurones[12] which we confirmed.

Seventeen rats (210–370 g) of both sexes were anaesthetized with chloralhydrate, 350 mg per kg intraperitoneally and additional doses given when necessary. The left VM was stimulated through a stereotaxically placed bipolar electrode with 1.0–1.5 mm tip separation, using 0.1-ms pulses and currents usually of 0.1–0.5 mA (rarely up to 1.2 mA) intensity. A recording microelectrode was lowered stereotaxically into the left SN. Extracellular single cell activity was monitored with glass-coated tungsten microelectrodes (exposed tips 5–10 μm long, 2.0–3.5 μm diameter), glued alongside three- or five-barrelled glass pipettes. The tungsten electrodes protruded 12–70 μm (mean 23 μm). Tip diameters of individual pipette barrels were 2.0–2.5 μm. Iontophoresis barrels contained the following substances: dopamine hydrochloride (0.2 M, pH 4.5), γ-aminobutyric acid (GABA, 0.5 M, pH 7.2), sodium glutamate (0.5 M, pH 6.7) and fluphenazine (50 mM, pH 2.4, a gift of Squibb). Sodium chloride (2 M, pH 7.0) was used for current control and balancing current. Using standard amplification methods, cell activity was recorded with a ratemeter. All cells found to be sensitve to current alone were rejected. Antidromic excitation was established when at least two of the following criteria were fulfilled: stable latency at threshold, frequency following above 500 s^{-1}, or collision with spontaneous impulses. The positions of the stimulating electrode and of each recorded cell were reconstructed histologically after small electrolytic lesions.

DA cells of pars compacta were distinguished from reticulata cells by both their histological localization and characteristic discharge pattern. They had impulses of long duration (2.71 $\pm$ 0.77 ms, mean $\pm$s.d. compared with 1.06 $\pm$ 0.25 ms for reticulata cells; 300 Hz, $-$3dB filtering), in agreement with earlier reports[1,4,14]. Pars compacta neurones always had a low spontaneous discharge frequency (less than 8 impulses per s) whereas reticulata neurones fired with a wide range of frequencies (2–60 impulses per s).

Of 89 reticulata cells 34(39%) were activated by iontophoretically applied DA (at least 33% above the level of spontaneous activity), using currents of 25 to 200 nA (mean 97 $\pm$ 60 nA for 100% augmentation) (Fig. 1a–d). Inhibitory responses were not observed with reticulata neurones. Forty-eight

* To whom correspondence should be addressed.

reticulata neurones (55%) responded antidromically to VM thalamus stimulation with latencies of 1.75 ± 1.00 ms, in agreement with known data[13]. Of the 48 nigrothalamic neurones 16 (33%) were excited by DA. Iontophoretically applied fluphenazine, a relatively specific dopamine receptor blocker[15], prevented or greatly attenuated the response to DA in seven cells, with currents of 100 or 200 nA and onset times ranging from 4 to 60 min. A clear blocking effect was not observed with four additional cells, probably because we had not recorded long enough during fluphenazine application. The responses to glutamate or GABA remained unchanged during fluphenazine application (Fig. 1d). Fluphenazine-induced DA blockade was found to be reversible in three cases.

In contrast to reticulata neurones, the spontaneous activity of pars compacta DA neurones was depressed by iontophoretically applied DA (12 of 15 neurones) (Fig. 1e). Excitation never occurred. Currents of 25 to 100 nA (mean 48 ± 22 nA) were required for a 50% reduction of activity. The DA effect was blocked by iontophoretically applied fluphenazine in all eight cases tested, in one case reversibly.

Higher currents of DA were required to depress the activity of dopaminergic neurones than in previous studies where recording was done through one barrel of a multibarrelled pipette[12]. This may have been due to the greater distance between the recording and drug applying sites in our electrodes[16,17]. Therefore, the currents necessary for DA to activate reticulata neurones should be lower than those in our experiments when recording with multibarrelled pipettes.

The present data show a remarkable difference in the DA effects: depression of activity with pars compacta dopaminergic neurones, but activation with reticulata neurones. In striatum, DA has a predominantly depressant effect[18,19], but activations were also observed[18]. In SN, the dopaminergic neurones of pars compacta are depressed but not excited by DA[12]. Neurones histologically localized in pars reticulata are so far reported to be activated as well as depressed by DA[20]. With the additional electrophysiological criteria of this study we found that the dopaminergic and non-dopaminergic neurones of SN responded in opposite ways to iontophoretically applied DA. The mechanisms underlying these two DA effects are not yet fully understood. DA could have direct inhibitory and excitatory effects on the two types of SN cells. Alternatively, DA might activate reticulata neurones by influencing the transmitter release of afferent axonal terminals, although direct experimental evidence is as yet lacking.

Striato–nigro–thalamic connections were recently throught to function as an output of the striatum distinct from the striato-pallido–thalamic system[21]. In our study a considerable proportion of nigrothalamic neurones were found to be influenced by DA. Systemically administered amphetamine also leads to activation of reticulata neurones, and slowing of DA neurones[22]. This effect could well be mediated by its known DA releasing action from dendrites in SN[23-25]. Therefore, it may be envisaged that DA is released functionally from dendrites and influences reticulata neurones. In this way the DA system would have an output to VM thalamus directly at the level of SN without involving the striatum. VM projects to layer I of wide areas of rat cerebral cortex[26]. This pattern of terminal distribution suggests a widespread, nonspecific action of impulses ascending from VM thalamus. Through its direct action on nigrothalamic cells, as suggested by our data, the DA system would exert an influence over large areas of the cerebral cortex.

Fig. 1 Ratemeter recordings of three cells in substantia nigra. *a–c*, Recording of a cell in pars reticulata. Iontophoresis of DA$^+$ increased the discharge rate (*a*). No effect of Na$^+$-carried current alone. Iontophoretically applied fluphenazine (Flu$^+$) greatly attenuated the response to DA (*b*); and the blockade was reversible (*c*). The onset of the drug effect was delayed because the electrode used had a large longitudinal distance (70 μm) between the tips of the recording electrode and the iontophoresis barrels [16,17]. (*d*) Recordings of another reticulata cell before (left) and during (right) Flu$^+$ application. The response to DA was suppressed by fluphenazine, but the glutamate (Glu) effect remained unaltered, thus demonstrating the specificity of the response. Onset of right recording was 75 min after onset of Flu$^+$ iontophoresis. DA and Glu were ejected with current compensation. (*e*) Activity of a pars compacta DA cell was depressed by DA. The effect was blocked during fluphenazine application but the blockade was not reversible during the time studied. Fluphenazine did not block the depressing effect of GABA.

Selective development of tolerance without dependence in multiple opiate receptors of mouse vas deferens

Rüdiger Schulz, Michael Wüster, Heinz Krenss & Albert Herz

Department of Neuropharmacology, Max-Planck-Institut für Psychiatrie, Kraepelinstrasse 2, D-8000 München 40, FRG

Studies with isolated tissues have provided strong indications for a multiplicity of opiate receptors[1-4]. To satisfy the definition of cross-tolerance (tolerance to a specific opioid implying tolerance to all opioids), chronic exposure to an opiate agonist should cause tolerance and dependence in all opiate-sensitive systems. On the other hand, if multiplicity of opiate receptors is defined in terms of multiple recognition sites whose activation by specific opioids cause independent responses, then development of cross-tolerance is less likely. The mouse vas deferens (MVD) provides a useful model to test these considerations. This tissue contains δ-opiate receptors, for which D-Ala^2-D-Leu^5-enkephalin (DADL) represents the most selective agonist, as well as μ-receptors, for which sufentanyl appears highly selective[3,5-7]. We report here that isolated vasa deferentia of mice chronically treated with DADL are 800-fold less sensitive to this δ-receptor agonist, whereas there is no cross-tolerance to μ-receptor agonists. On the other hand, chronic exposure of mice to sufentanyl renders their vasa deferentia more than 1,000-fold less sensitive to sufentanyl, but affects their sensitivity to DADL insignificantly. Apparently, such highly tolerant preparations exhibit no detectable sign of dependence when challenged with naloxone or clonidine. These findings favour the notion that opiate tolerance and dependence dissociate in the MVD.

Mice (NMRI, 25 g) were treated chronically from osmotic minipumps with either DADL or sufentanyl. Vasa deferentia were removed from the animals and set up for electrical stimulation[4]. To prevent unmasking of opiate receptors, the bathing solution contained DADL or sufentanyl at the concentration measured in the serum. After equilibration dose–response curves were established and the drug concentrations required to inhibit electrically evoked twitches by 50% were determined (IC$_{50}$). Tests for dependence were conducted in the presence of the narcotic agonist using naloxone as antagonist.

The effect of chronic DADL infusion on vasa deferentia is shown in Fig. 1. Dose–response curves for DADL were shifted to the right, indicating development of tolerance (Fig. 1a). The degree of the shift was dependent on the amount of DADL infused—administration of 5 µg DADL per h for 6 days resulted in an 800-fold shift (IC$_{50}$ 4×10^{-7} M; naive 5×10^{-10} M). Vasa deferentia taken from DADL-treated animals, which were set up in the presence of 20 nM DADL, displayed a similar twitch tension evoked by electrical stimulation as compared to naive tissues in the absence of any drug. Washing highly tolerant preparations (5 µg DADL per h, 6 d) for 3 h with drug-free Krebs–Ringer solution increased the sensitivity to DADL slightly (IC$_{50}$ 1×10^{-7} M) and the sensitivity was not further increased by a 5-h wash procedure. In vasa deferentia taken from mice infused with 5 µg DADL per h for 24 h, only a 200-fold shift of the dose–response curve was found (IC$_{50}$ 8×10^{-8} M). Washing these preparations for 2 h with drug-free Krebs–Ringer solution resulted in a considerable loss of tolerance (IC$_{50}$ 9×10^{-10} M). Figure 1b shows dose–response curves for sufentanyl, normorphine and clonidine on vasa deferentia of naive and DADL-infused (5 µg per h, 6 d) mice. Although the vasa deferentia are highly tolerant to the δ-receptor agonist DADL, the IC$_{50}$ for normorphine was not

changed and only a fourfold increase was observed for sufentanyl. As opiate dependence is associated with subsensitivity to clonidine, additional tests were conducted with this α-adrenoreceptor agonist[8]. The IC$_{50}$ value of clonidine was not changed in tolerant preparations challenged in the presence of naloxone (200 nM).

Figure 2 shows dose–response curves for sufentanyl and DADL on vasa deferentia from untreated mice and from mice infused for 6 d with sufentanyl at a delivery rate of 10 µg per h. Again, to prevent unmasking of opiate receptors *in vitro*, the tissues of chronically treated mice were set up in the presence of 5 nM sufentanyl, the corresponding serum concentration. Sufentanyl was over 1,000-fold less potent (IC$_{50}$ 50 nM) in vasa deferentia taken from sufentanyl-treated animals as compared to naive preparations (IC$_{50}$ 0.04 nM). A high degree of cross-tolerance with normorphine was found in such preparations. In contrast, DADL showed identical activities in control and sufentanyl-tolerant vasa deferentia, as does, for example, Leu-enkephalin (details to be published elsewhere).

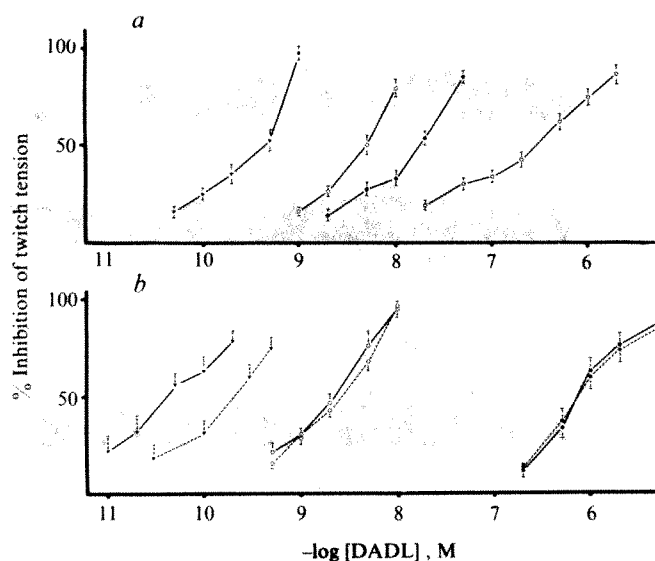
Highly tolerant vasa deferentia from mice chronically infused with DADL (5 µg per h, 6 d) were challenged with naloxone (50–1,000 nM) in the presence of 20 nM DADL. Neither basic tension (absence of electrical stimulation) nor electrically evoked twitch tension was affected by the narcotic antagonist. However, naloxone completely antagonized the inhibition of


Fig. 1 *a*, Dose–response curves for D-Ala^2-D-Leu^5-enkephalin (DADL) on the electrically stimulated isolated mouse vas deferens (0.1 Hz, 0.5 ms, 40 V; basic tension 0.05 g). Data are for preparations from untreated mice (▼) and from mice infused with 0.5 µg DADL per h (○), 1.5 µg per h (●) and 5 µg per h (□) for 6 d. Infusion was from osmotic minipumps (Alza model 1701) implanted subcutaneously, which release 1 µl per h. The preparations taken from chronically DADL-treated mice were incubated *in vitro* with their corresponding serum DADL concentrations, which was 1 nM in mice receiving 0.5 µg per h, 3 nM in mice infused with 1.5 µg per h and 20 nM during infusion of 5 µg per h as determined in the isolated vas deferens. These data are the means of three to five serum samples from different mice assayed the 2nd, 4th and 6th days of the experiment. The maximal standard error of the mean serum data was <15%. *b*, Dose–response curves for sufentanyl (▽), clonidine (○) and normorphine (●) on vasa deferentia taken from non-pretreated mice and from mice infused for 6 d with 5 µg DADL. Preparations from chronically treated mice were set up for electrical stimulation in the presence of DADL (20 nM). Dotted lines represent curves obtained from vasa deferentia of infused mice. A period of 30 min was allowed for equilibration after set-up in the presence of the enkephalin derivative with changes of the bath fluid every 5–10 min. Each point on the figure is the mean of at least six tests on tissues from different animals. Vertical bars indicate standard errors.
Fig. 2 Dose–response curves for sufentanyl (squares) and DADL (circles) on vasa deferentia of naive mice (open symbols), and from those infused for 6 days with 10 µg sufentanyl per h (solid symbols). The preparations of chronically treated mice were set up in the presence of 5 nM sufentanyl, the respective drug concentrations in the serum at the time of killing. Each point is the mean of at least eight determinations on tissues of different animals. Vertical bars represent s.e.m.

twitch tension produced by 10^{-6} M DADL, without an overshoot increase in tension. Similarly, no signs of withdrawal were demonstrated in sufentanyl-tolerant preparations.

The findings reported here unequivocally point to a multiplicity of opiate receptors. Selective activation of a specific population of opiate receptors, δ-receptors, for prolonged periods causes their selective desensitization (that is, tolerance), leaving the responsiveness of µ-receptors unaffected. By analogy, tolerance of the µ-receptor develops upon their chronic activation without affecting the responsiveness of δ-receptors. Thus, these data conflict with the classical notion that cross-tolerance reflects a general characteristic of opiates. The lack of cross-tolerance between δ-receptor agonists and µ-receptor agonists does not exclude, however, a mutual receptor activation at sufficiently high concentrations of these compounds.

One aspect of the present investigations relates to the phenomenon of dependence, which has been postulated to be invariably accompanied with tolerance[9,10]. Although the vasa deferentia exhibited an extremely high degree of tolerance, no signs of dependence were observed on challenge with naloxone or clonidine. The response to each of the drugs is considered a reliable test for dependence in opiate-tolerant tissues from the myenteric plexus of the guinea pig[8,11]. Although a dissociation of tolerance and dependence conflicts with the common understanding of the mechanisms underlying these phenomena[12-14], an adaptation to chronic opiate receptor activation by a reduction of opiate binding sites[15] could explain our findings. Moreover, we have some evidence that chronic DADL infusion in mice results in a reduction of the number of δ-receptors in the MVD. Such a mechanism of adaptation resembles that involved in desensitization of neurohormone receptors on chronic activation[16-18].

Dopaminergic stimulation of prolactin release

Carl Denef, Danielle Manet & Raymonde Dewals

Laboratory of Cell Pharmacology, Department of Pharmacology, Leuven, School of Medicine, Campus Gasthuisberg, K.U. B-3000 Leuven, Belgium

Prolactin (PRL) secretion from anterior pituitary is believed to be under tonic inhibitory control of dopamine (DA)[1] released from the tubero-infundibular dopaminergic neurones into the hypophysial portal blood[2-4]. Inhibition of PRL release by DA seems to be mediated by stereospecific DA receptors located in PRL cells[5,6]. Apomorphine and various ergot alkaloids such as bromocryptine mimic the inhibitory effect of DA both in *vivo* and *in vitro*, presumably by a direct agonist action on these 'inhibitory' receptors[1,6,7]. We now report that PRL secretion in primary cultures of rat pituitary cells can be stimulated by DA when concentrations a thousand times lower than those required for inhibition are used. Secretion rates above basal release can also be induced by apomorphine and bromocryptine when the 'inhibitory' receptors are blocked with certain DA receptor antagonists.

Rat pituitary cells from adult male Wistar rats (300–350 g) maintained in monolayer culture[7,8] and superfused pituitary cells cultured on polystyrene beads (Biosilon, Nunc) were used. All tests were done after a period of 5 days in culture. PRL was measured using a specific rat PRL radioimmunoassay using the kits and procedures from the NIAMDD Pituitary Hormone Distribution Program, Bethesda, Maryland. Statistical analysis of the data was by multiple *t*-test.

Figure 1 shows the effect of DA in both these cell systems. In monolayer cultures picomolar concentrations of DA stimulated PRL release by more than 50% ($P < 0.001$), whereas inhibition occurred from concentrations about a thousand times higher. In superfused cells there was an 82% rise in average secretion rates during superfusion with 1–100 pM DA, compared with maintained average secretion rate during superfusion with the control medium ($P < 0.001$). Average secretion rates were 3.78 ± 0.15 ng min^{-1} and 2.08 ± 0.12 ng min^{-1}, respectively (mean ± s.e.m.). When DA was superfused together with 10 nM of the DA receptor antagonists haloperidol or (+)butaclamol, stimulation was 56% and 107% above basal release, respectively. Thus, stimulation by DA seemed to be partially antagonized by a 'low' concentration of haloperidol but not by (+)butaclamol.

Apomorphine was more potent than DA in suppressing PRL release (EC$_{50}$ 0.95 nM and 14 nM, respectively) but, as shown in Fig. 2, it had only a marginal, if any, stimulatory effect. However, when co-incubated with 10 nM of the DA receptor antagonist haloperidol, picomolar concentrations of apomorphine stimulated PRL release to ~30% above basal secretion rates ($P < 0.01$); such stimulation was not seen when haloperidol was added alone. Similar results were obtained in superfused cells. Picomolar concentrations of apomorphine also stimulated PRL release when co-incubated with 10 nM domperidone or
Fig. 1 Effect of dopamine (DA) alone or together with 10 nM haloperidol (HAL) or (+)butaclamol (BUT) on PRL secretion from primary cultures of dispersed rat pituitary cells (male Wistar rats, 300–350 g). The amount of PRL secreted in the medium is expressed in ng equivalents of the reference preparation NIAMDD rat-PRL-RP-1. *a, Monolayer cultures.* The culture method was as described previously[7,8]. Cells were plated in multiwell Petri plates (Falcon 308) at 2x 10^5 cells per well. Culture medium was Dulbecco's modified Eagle's medium (DMEM), supplemented as before[8] with 10% horse serum, 2.5% fetal calf serum, non-essential amino acids (all from Gibco) and antibiotics. Tests were performed on the fifth day in culture. The cultures were washed with Earle's balanced salt solution (EBSS) (Gibco), preincubated in EBSS for 1 h at 37 °C in a CO_2/air incubator, washed again and incubated for 4 h at 37°C in a CO_2/air incubator in 500 μl EBSS, pH 7.6, containing the test substances. The various concentrations of DA (Sigma), freshly dissolved and further diluted in 1% ascorbic acid and of the DA receptor antagonists (Janssen) dissolved and further diluted in ethanol were added in 5-μl aliquots. Controls received the vehicles alone. After incubation the media were collected, bovine serum albumin (BSA) added to a final concentration of 0.1%, centrifuged and the supernatants stored at −25 °C until assayed. Each value represents the mean ± s.e.m. of 6 replicate wells. *b, Superfused cell cultures.* Dispersed pituitary cells suspended in 1 ml culture medium were allowed to settle on polystyrene beads (Biosilon, Nunc average diameter 330 μm) packed in a 1-ml sterile syringe the bottom of which was closed with a 25-μm nylon mesh. Homogenous distribution was obtained by pumping the cell suspension through the column of beads at low flow rate (1 ml h⁻¹). The beads had been pretreated with poly-L-lysine[29,30] to ensure instant and irreversible attachment of the cells[8,29]. Approximately 10–15 × 10⁶ cells were loaded on 2 × 10⁵ beads. After washing with the same suspending medium the beads were gently transferred to an untreated plastic Petri dish and maintained in culture medium (see *a*). After 5 days in culture microscopic examination showed that the cells had made individual monolayers over the bead surface, although small aggregates of cells were seen on some beads. The superfusion system consisted of a small plastic column (diameter 5 mm), the bottom of which was closed with a 25-μm nylon mesh and connected to a peristaltic pump. The column and connecting tubings were mounted in a waterbath at 37 °C. To minimize adsorption of drugs, plastic containers, columns and connecting tubings were rinsed before each experiment with 1% BSA in phosphate-buffered saline. A number of beads, containing ~3–4 × 10⁶ cells, were packed on the bottom of each column and the peristaltic pump superfused the beads with DMEM at a flow rate of 1 ml min⁻¹. The volume of medium covering the beads was maintained at 1 ml. Before the control and test substances were added (dissolved and diluted as in *a*), the cells were allowed to equilibrate for 40–60 min with DMEM. Subsequently, 2-ml fractions were collected every 2 min, BSA added as in *a* and the samples stored at -25°C until assayed.

100 nM halopemide, a substituted benzamide structurally related to the butyrophenones but with a distinct pharmacological profile[9]. As expected[1,6,7], the DA receptor antagonists completely prevented inhibition by nanomolar concentrations of apomorphine. Thus, it is reasonable to assume that the DA receptor antagonists potentiate the stimulatory action of apomorphine because at the concentrations used they completely block the 'inhibitory' DA receptors but do not, or only partly, block those receptors which mediate stimulation of PRL release. Note that maximal stimulation by apomorphine was seen at concentrations similar to those of DA but that, in contrast to DA, the magnitude of the effect was less, and slightly higher concentrations even antagonized the stimulatory effect. This seems to indicate that apomorphine has a lower intrinsic activity than DA. Moreover, stimulatory concentrations of apomorphine (10–100 pM) were closer to inhibitory concentrations (0.25–10 nM) than was the case with DA (1–100 pM against 1–100 nM) and this may explain why apomorphine, when applied alone, was not capable of enhancing secretion.

As shown in Fig. 3, bromocryptine was extremely potent in suppressing PRL release. Concentrations as low as 10⁻¹⁸ M were already effective. Co-incubation with 0.1 or 1 nM haloperidol or domperidone shifted inhibition by bromocryptine towards higher concentrations but, from about 10⁻¹² M bromocryptine, PRL release again increased ($P < 0.01$ or 0.001). When incubated with 10 nM of the DA antagonists, bromocryptine stimulated PRL release above basal secretion rates

($P < 0.001$). This occurred at concentrations entirely overlapping with the inhibitory concentrations.

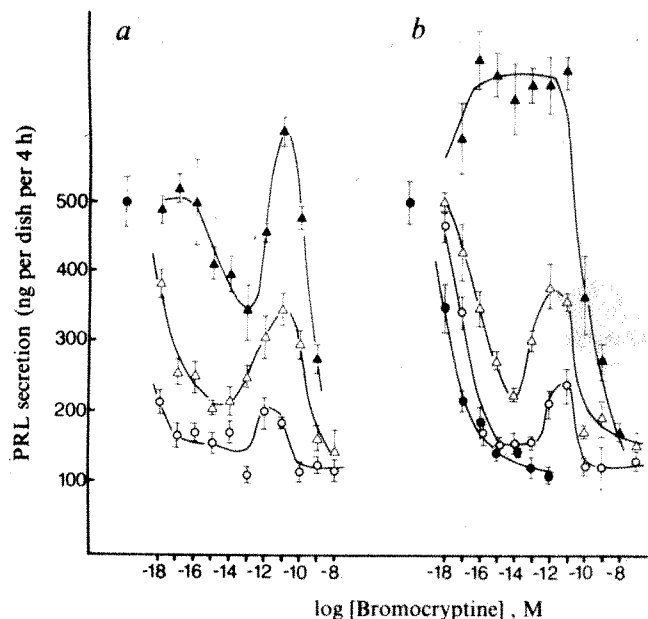
These experiments show that, in addition to their inhibitory effects on PRL release, DA and the DA receptor agonists apomorphine and bromocryptine have a stimulatory potency. In 5-day-old rat pituitary cell cultures, DA stimulated PRL release at concentrations as low as 1 pM, about 1,000 times lower than concentrations that cause inhibition. Picomolar concentrations of apomorphine and even lower concentrations of bromocryptine were also stimulatory, although this effect was seen only when inhibition was prevented by certain DA receptor antagonists. As apomorphine and bromocryptine are highly specific ligands of DA receptors[10,11], these findings strongly suggest that the 'stimulatory' receptors are specific DA receptors. Moreover, data indicate that these DA receptors are different from receptors that mediate inhibition. First, the relative stimulatory potencies of DA, apomorphine and bromocryptine were different from those for inhibition. DA stimulated PRL release from concentrations considerably lower than those causing inhibition, whereas apomorphine and bromocryptine stimulated release at concentrations closer to or overlapping inhibitory concentrations. Second, stimulation by DA could be antagonized, at least partially, by 10 nM haloperidol, but not by 10 nM (+)butaclamol, a DA receptor antagonist that is more potent than haloperidol in preventing the dopaminergic inhibition of PRL release[6,7]. It might be argued that stimulation is mediated by the inhibitory receptor in a different functional

Fig. 2 Effect of apomorphine alone (O) or together with 10 nM haloperidol (●), domperidone (■) or halopemide (100 nM) (▲) on PRL secretion from primary cultures of dispersed rat pituitary cells. Methods as in Fig. 1. *a*, Monolayer cultures, means ± s.e.m. of six replicate wells. *b*, Superfused cells.
state which would exist only at low receptor occupancy. However, if this were so, it would be difficult to explain apomorphine stimulation in conditions where virtually all inhibitory receptors were occupied by a DA receptor antagonist. Thus, the action of DA on PRL release rather involves two different receptors or receptor sites.

Evidence for more than one DA receptor type has already been given for a number of tissues, particularly the brain[10,12-14].

Fig. 3 Effect of bromocryptine alone (●) or together with: *a*, 0.1 nM (O), 1 nM (△) and 10nM (▲) haloperidol; or *b*, domperidone, on PRL release from primary cultures of dispersed rat pituitary cells. Monolayer culture method as in Fig. 1. Bromocryptine (Sandoz) was dissolved and further diluted in ethanol. Means ± s.e.m. of six replicate wells.

Various receptor categories have been recognized on the basis of: their differential specificity for DA receptor agonists and antagonists[10,15-20]; differential sensitivity of behavioural[11,21,22] and electrophysiological[23] responses to DA agonists; adenyl cyclase activation[10,24]; and regulation by guanine nucleotides[25]. Recent work by Sibley and Creese has suggested that there may be a DA receptor in the anterior pituitary distinct from the receptor that mediates inhibition of PRL release[26]. This DA rereceptor seems to be regulated by guanine nucleotides and is possibly linked to adenyl cyclase. It is tempting to hypothesize that this receptor is involved in stimulation of PRL release by DA. However, the fact that DA agonist activity at this receptor is exerted at micromolar concentrations[26] is difficult to reconcile with the finding here that stimulation of PRL release is evoked at picomolar concentrations. By contrast, the receptors involved in stimulation of PRL release seem to have certain characteristics in common with the DA 'autoreceptors' on cell bodies or terminals of nigrostriatal dopaminergic neurones[23]: the latter receptors are much more sensitive to DA[23] than adenyl cyclase-linked postsynaptic DA receptors in the striatum[23]; apomorphine and bromocryptine both appear to be agonists of these receptors[11,19,22,23]; and haloperidol is a considerably more potent antagonist than (+)butaclamol[19]. Thus, certain characteristics of DA autoreceptors seem to correspond with those of pituitary receptors involved in dopaminergic stimulation of PRL release.

Thus the data presented here suggest that dopaminergic control of PRL secretion at the level of the PRL cells may involve two different receptors for DA, one being inhibitory and the other stimulatory. This is most intriguing in view of the fact that PRL release is believed to be under tonic inhibitory control by DA[1]. The average concentration of DA reported in hypophyseal portal blood of male rats is 0.25 ng ml^{-1} (about 1.3 nM)[4]. This concentration is far below that required for maximal inhibition of PRL release *in vitro* as well as *in vivo*[27] and close to the stimulatory concentrations found here. At such a concentration it is likely that the effect of DA on PRL secretion


depends on the relative contribution of stimulatory and inhibitory effects. It seems, therefore, that the role of DA in control of PRL secretion is not just one of tonic inhibition. Changes in the relationship between 'stimulatory' and 'inhibitory' receptors could be one of the mechanisms underlying the dynamic regulation of PRL release by DA.

Inhibin is absent from azoospermic semen of infertile men

R. S. Scott & H. G. Burger

Medical Research Centre, Prince Henry's Hospital, Melbourne 3004, Australia

There is ample evidence that the secretion of follicle stimulating hormone (FSH) by the pituitary gland is regulated by a nonsteroidal hormone of gonadal origin, termed inhibin[1-3]. In several species, testicular extracts[4], gonadal lymph[5] and seminal plasma[6] have been shown to contain proteins which inhibit FSH release; lack of suitable assays for inhibin has, however, prevented clear definition of its physiological significance. Men whose testes show the histological changes of germinal cell failure usually have raised FSH levels in the blood, but may have normal levels of luteinizing hormone (LH) and testosterone[7]. Such patients would thus be predicted to show reduced inhibin production. To test this, we have measured the FSH inhibitory activity of seminal plasma from azoospermic subjects with raised plasma FSH levels. We report here our confirmation of diminished inhibin levels in seminal plasma of these patients, thus providing convincing support for its physiological role as a modulator of FSH production in man.

Our subjects were eight patients with idiopathic azoospermia and raised serum FSH levels, who were attending the Infertility Clinic at Prince Henry's Hospital (Table 1). Testicular histology of three of these patients showed changes of Sertoli-cell-only syndrome, seminiferous tubule hyalinization and moderate hypospermatogenesis, respectively. Levels of LH, although higher than in eight control men with normal semen analyses, were within the laboratory normal range (0.6–3.6. IU l^{-1}). For the purpose of this study, we considered a normal semen analysis to comprise a sperm count $>20 \times 10^6$ per ml, sperm motility $>60\%$ and normal sperm morphology. FSH inhibitory activity was also measured in semen from three patients with non-functioning testicular tissue. One patient with Klinefelter's syndrome had testicles of approximately 1 cm³ (plasma FSH 30.2, LH 9.4 IU l^{-1}). The other two patients were found at operation to have small bilateral abdominal testicles. Plasma FSH levels were 17.0, 23.7 IU l^{-1} and LH levels 9.4, 4.2 IU l^{-1}. Neither was on androgen replacement treatment at the time of collection of semen samples preoperatively. Seminal plasma collected from six patients between 2 and 8 months post-vasectomy was used as an azoospermic control as vasal

obstruction does not affect the integrity of the seminiferous epithelium.

Semen samples were centrifuged twice at 3,000g for 30 min and the plasma separated. An equal volume of charcoal (Merck), 200 mg ml⁻¹ in phosphate-buffered saline (CSL, Melbourne), was added to each sample. After allowing the samples to stand for 24 h at 4 °C, the charcoal was removed by two centrifugations at 4,000g for 30 min at 4 °C. Charcoal was used to remove poorly defined small molecular weight substances that seem to interfere with the assay by causing nonspecific toxic changes.

Inhibin-like activity was measured in combined, multiple parallel line bioassays[8,9], in which the unknowns were expressed in terms of an inhibin standard derived from ovine testicular lymph (OTLP)[10], arbitrary potency 1 U per mg. The inhibin standard was added to dispersed rat anterior pituitary cell cultures over a dose range of 0.156–2.5 mg ml⁻¹ (Fig. 1). Semen samples were assayed in quadruplicate at four or five dilutions up to a maximum concentration of 50 μl seminal plasma per ml of incubation medium. At the end of the 72-h incubation period, the cells were lysed and FSH and LH were measured in the lysate (Fig. 1 legend)[9]. Lack of change of LH content was used as an index of the specificity of the inhibitory response (Fig. 1).

Table 1 Sperm counts, FSH, LH and testosterone levels* in eight normal and eight infertile patients

Group	n	FSH (IU l^{-1})	LH (IU l^{-1})	Testosterone (nmol l^{-1})	Sperm count (10^6 ml⁻¹)
Azoospermic	8	11.7 (6.8–17.0)	2.3 (1.5–3.8)	20.0 (15.0–24.0)	0
Normal	8	2.1 (1.5–2.9)	1.0 (0.7–1.8)	22.0 (13.0–42.0)	73 (22–170)

* Median (and range).

In the eight normal subjects, dose–response lines were significantly parallel to the reference standard; the samples had relative potencies of 20.8–60.0 U ml⁻¹ of inhibin activity (Fig. 2). In men with azoospermia (Fig. 2), the inhibin activity in the seminal plasma was undetectable (<2.5 U ml⁻¹ in five men) or low (<6.3 U ml⁻¹ in three men). A dose–response curve could not be obtained, because addition of seminal plasma at concentrations above 50 μl ml⁻¹ to pituitary cell cultures was often followed by morphological changes, suggesting a toxic effect, and a concomitant reduction of LH content. No FSH inhibitory activity was detectable in the semen of the three patients with testicles of small size. The six post-vasectomy samples had

measurable inhibin-like activities ranging from 4.5 to 20.2 U ml⁻¹ (mean 15.5 U ml⁻¹, s.d. 5.8 U ml⁻¹), significantly less than for normal subjects although higher than found in patients with germ cell failure.

To exclude the possibility that azoospermic seminal plasma in these patients contained a factor blocking the action of inhibin, we added inhibin derived from OTLP or human follicular fluid to azoospermic seminal plasma. In both cases, the predicted inhibition of cell content of FSH was observed, without significant change of the dose–response curve.

Although a considerable body of data suggests the existence of a non-steroidal regulator of pituitary FSH secretion[1-3], the relationship exists between the cell population of the epithelium spontaneous disorders of the seminiferous epithelium has not been studied. It has been previously shown that a reciprocal relationship exists between the cell population of the epithelium and serum FSH, and that serum FSH levels are uniformly elevated only in the presence of severe seminiferous tubule damage[11]. In the absence of a well characterized purified preparation of inhibin, physiological studies must rely on specific
Fig. 1 FSH and LH content in 22 experiments (mean ± s.e.m.) using OTLP standard as the inhibin source. Similar dose responses of FSH, with lack of LH change, were observed after addition of treated normal human seminal plasma. Dispersed pituitary cells were prepared by enzymatic methods in sterile conditions[9,10]. Aliquots (0.5 ml) of medium containing 125,000 cells were added to each well of tissue culture plates (Coster, 3524) and incubated for 24 h at 37 °C in 5% CO_2, 95% air before adding semen samples and OTLP standard. All preparations were added in quadruplicate at four or five dilutions. After a further 72 h in culture, the medium was aspirated and discarded, and 0.5 ml of phosphate buffer containing 0.1% Triton X-100 was added to each well. This causes detachment and lysis of cells, releasing intracellular hormone into the buffer. Standards for hormones measured in the lysate were rat FSH-RP1 and rat LH-14 (NIAMDD)[9,12]. The FSH and LH concentrations were expressed as % of control (no added inhibin) and regression analysis of the FSH dose-response lines carried out by computer, calculating slope (*b*), index of precision (λ) and significance of regression (Finney's *g*)[13]. In 22 experiments using the reference standard (OTLP): −*b* = 24.0 (19.2–31.4), −λ = 0.06 (0.032–0.110) and Finney's *g* = 0.01 (0.003–0.057). Median and range are given. Interassay variation of three unknown preparations was 20.1%, 19.8% and 15.0%. Specificity is satisfactory as changes of rat LH, GH or prolactin were not significant[9]. Bioassay potency estimates of unknown preparations were similar using the more conventional methods of *in vitro* assay measuring LH-releasing hormone stimulated release[9]. From eight separate experiments, four wells per experiment, the FSH content (of control wells) at the end of 96 h culture was 636 ± 28.0 ng per 125,000 cells.

bioassay. The present results have been obtained with a reproducible assay in which the cell content of FSH, but not LH, is decreased by inhibin-containing preparations[9]. In men with severe seminiferous tubule disease, as shown by elevated levels of serum FSH and azoospermia, seminal plasma levels of inhibin are low or undetectable. These patients had normal peripheral plasma testosterone concentrations, suggesting that the elevations of serum FSH represent a release from the negative feedback influence of this inhibitor.
Fig. 2 FSH inhibitory activity in human seminal plasma of normal, post-vasectomized and azoospermic infertile patients. The assay limit for measurement of inhibin was 2.5 U ml⁻¹ (indicated by shading).

Seminal plasma of vasectomized patients contained FSH inhibitory activity; this suggested secretion and perhaps concentration of inhibin in the prostatic and seminal vesicular fluid. However, this does not imply extragonadal production of this inhibitor, because the levels of inhibin were low in infertile subjects despite the presence of normal concentrations of testosterone, the major factor maintaining prostatic function. Therefore, the likely source of this material is the testis, as the only difference between groups was the integrity of the germinal epithelium. Further support for the testicular production of this inhibitor is provided by the observation that no inhibin was present in the semen of the two subjects with abdominal testes or the patient with Klinefelter's syndrome. Such findings suggest a causal relationship between seminiferous tubular disease and decreased production of inhibin.

Note added in proof: A substance which diminished FSH levels in castrated male rats was found to be present in the seminal plasma of normal and oligospermic subjects, but was absent in subjects with azoospermia caused by inhibition of gametogenesis[14].

Renin-like effects of NGF evaluated using renin-angiotensin antagonists

D. B. Avrith, M. E. Lewis, & J. T. Fitzsimons

Physiological Laboratory, University of Cambridge, Cambridge CB2 3EG, UK

Intracranial injection of angiotensin II (AII) or activation of the cerebral isorenin–angiotensin system with intracranial renin causes an immediate thirst[1] and a delayed sodium appetite[2] in the rat. Nerve growth factor (NGF), a polypeptide trophic factor for peripheral sympathetic and sensory neurones[3], has also been reported to be a potent stimulus to thirst[4] and sodium appetite[5] when injected into the brain of the rat. Lewis et al.[5] drew attention to the marked similarity between the effects of 2.5S NGF and renin on thirst and sodium appetite and suggested that the NGF responses were mediated by the cerebral isorenin-angiotensin system. We report here that NGF-induced thirst and sodium appetite, as well as increased blood pressure and increased ornithine decarboxylase activity in the brain and liver, depend on the formation of AII (see also ref. 6).

To test the hypothesis that NGF-induced thirst and sodium appetite depend on the activation of the cerebral isorenin-angiotensin system[5], rats were pretreated with saralasin, a competitive antagonist of AII (ref. 7), or the converting enzyme inhibitors[8,9], SQ 20881 or SQ 14225. These inhibitors are effective in suppressing the thirst[10] and sodium appetite (unpublished results) elicited by intracranial administration of renin.

Intracranial injection of saralasin caused a dose-dependent inhibition of water intake induced by injection of 0.66 μg 2.5S NGF[11] through the same cannula (see Fig. 1 legend for method). In 1 h the intake of water after NGF injection was 15.3 ± 1.5 ml ($n = 18$), and this was reduced by saralasin pretreatment (1, 5 and 25 μg respectively) to 9.2 ± 2.6 ml ($n = 8$, $P < 0.05$), 6.3 ± 0.4 ml ($n = 4, P < 0.01$), and 4.4 ± 1.5 ml ($n = 6$, $P < 0.001$). The 1-h intake of 2.7% NaCl after NGF injection (2.4 ± 0.7 ml, $n = 18$) was completely abolished by 25 μg saralasin ($n = 6$, $P < 0.05$).

Intracranial injection of SQ 20881 (25 μg) or SQ 14225 (5 μg) resulted in complete inhibition of water intake during the first hour after administration of 0.66 μg 2.5S NGF through the same intracranial cannula (Fig. 1). The 18-h water and 2.7% NaCl intakes after NGF were unaffected by the single injection of 25 μg SQ 20881, but were attenuated significantly by the single injection of 5 μg of the more potent converting enzyme inhibitor, SQ 14225.

The effect of converting enzyme inhibition on the overnight intakes of water and 2.7% NaCl after NGF was further studied by infusing SQ 20881 throughout the 18 h of the experiment. Continuous infusion of the inhibitor resulted in a significant depression of the overnight water and 2.7%NaCl intakes after NGF injection (Fig. 1). The effect of NGF on thirst and sodium appetite is therefore indistinguishable from that of renin with respect to its dependence on generation of AII.

The renin-like activity of NGF preparations was further tested by measuring their pressor activity. Intravenous administration of dipsogenically active 7S NGF[12] produced a dose-dependent rise in arterial blood pressure (Fig. 2), as did 2.5S NGF (data not shown). The pressor responses to NGF were similar to those of equipotent doses of renin. The responses showed a slow onset over 1–2 min and lasted for up to 20 min. They were enhanced by nephrectomy and were completely abolished by pretreatment with 25 μg saralasin, 25 μg SQ 14225, or NGF antiserum[13]. In contrast, immunogenically

pure β NGF subunit[14] was devoid of pressor activity, and also had a smaller and more variable effect on thirst and sodium appetite compared with other preparations of NGF.

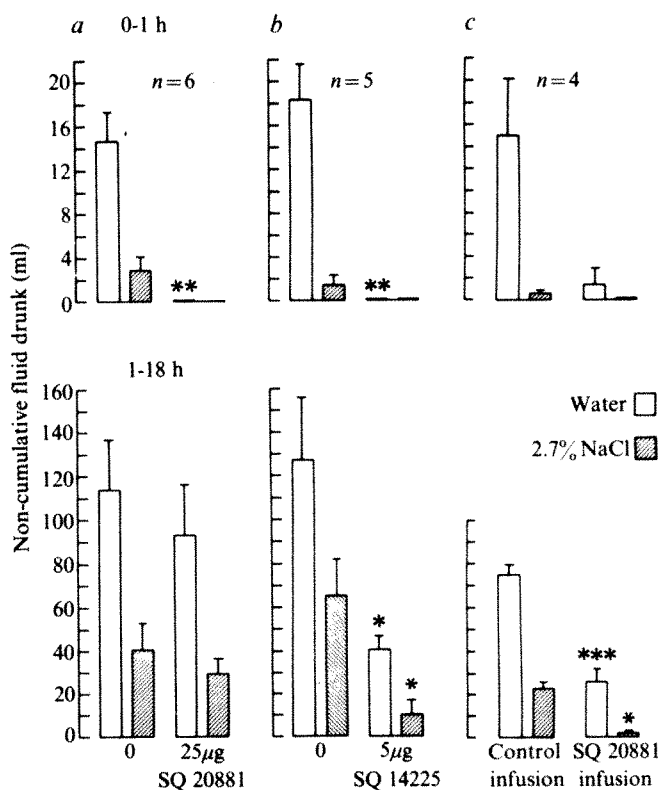
These findings raise the possiblity that other biological effects of NGF are caused by AII formed as a result of the action of the renin-like enzyme in NGF preparations. NGF has recently been reported to produce an increase in the activity of ornithine decarboxylase (ODC) in a variety of tissues[15,16], including brain[17] and liver[18]. In the present experiments intraventricular administration of either 7S NGF or renin was followed 6 h later by an increase in ODC activity in the brain and liver (Fig. 3). The enzyme induction and water intakes following intraventricular administration of either NGF or renin were reduced significantly by pretreatment with 35 μg SQ 14225. The dependence of the enzyme induction in brain and liver on AII formation is consistent with the recent finding that large doses of AII are an effective stimulus to ODC induction in these tissues[19]. Induction of ODC in the liver following NGF administration depends on activation of the pituitary-adrenal axis[18]. Furthermore, administration of NGF[20], like AII (refs 21–23), causes an increase in plasma ACTH and corticosteroids. Therefore, stimulation of ACTH by NGF preparations may depend on their content of renin-like enzymes.


Fig. 1 The effect of angiotensin converting enzyme inhibitors on NGF-induced thirst and sodium appetite. Five min before injection of 2.5S NGF into the preoptic area or third ventricle, rats were given intracranial injections (1 μl) of 0.9% NaCl (0, vehicle), or SQ 20881 (Bachem) (a), or SQ 14225 from Dr Z. P. Horowitz, Squibb (b). For intracranial infusions into the third ventricle (c), rats were first infused with either 3 μl of 0.9% NaCl (control) or 3 μl of 0.9% NaCl containing 25 μg SQ 20881 at the rate of 1 μl every 3 min. The injector was then removed and 0.66 μg 2.5S NGF in 4 μl 0.9% NaCl was aspirated into the tubing. The injector was replaced and the rats were infused with the solution at the same rate. After 12 min the infusion rate was changed so that the rats received 25 μg SQ 20881 every hour for 18 h. Control rats received 3 μl per h of 0.9% NaCl during this period. Water and 2.7% NaCl intakes were measured at 1 and 18 h after the start of the infusion of NGF. Results are expressed as mean ± s.e.m. The statistical significance of the differences between the control and inhibitor-treated rats was evaluated using Student's *t*-test. * $P < 0.05$; ** $P < 0.01$; *** $P < 0.001$.

Fig. 2 The effect of an angiotensin converting enzyme inhibitor (SQ 14225) or an angiotensin II receptor antagonist (saralasin, P113) or NGF antiserum on NGF-induced pressor responses. Blood pressure, before and after test injections into the right jugular vien, was recorded with a strain-gauge transducer from the carotid artery of the rat anaesthetised with urethane (1 g per kg body weight intraperitoneally) and ganglion-blockaded (50 mg hexamethonium per kg body weight subcutaneously, with additional amounts as required). Inhibitors were injected 5 min before NGF administration. Responsiveness to AII was always confirmed in animals which had failed to respond to NGF after pretreatment with SQ 14225 or NGF antiserum (8.3 μl diluted to 100 μl; from Dr G. Guroff).

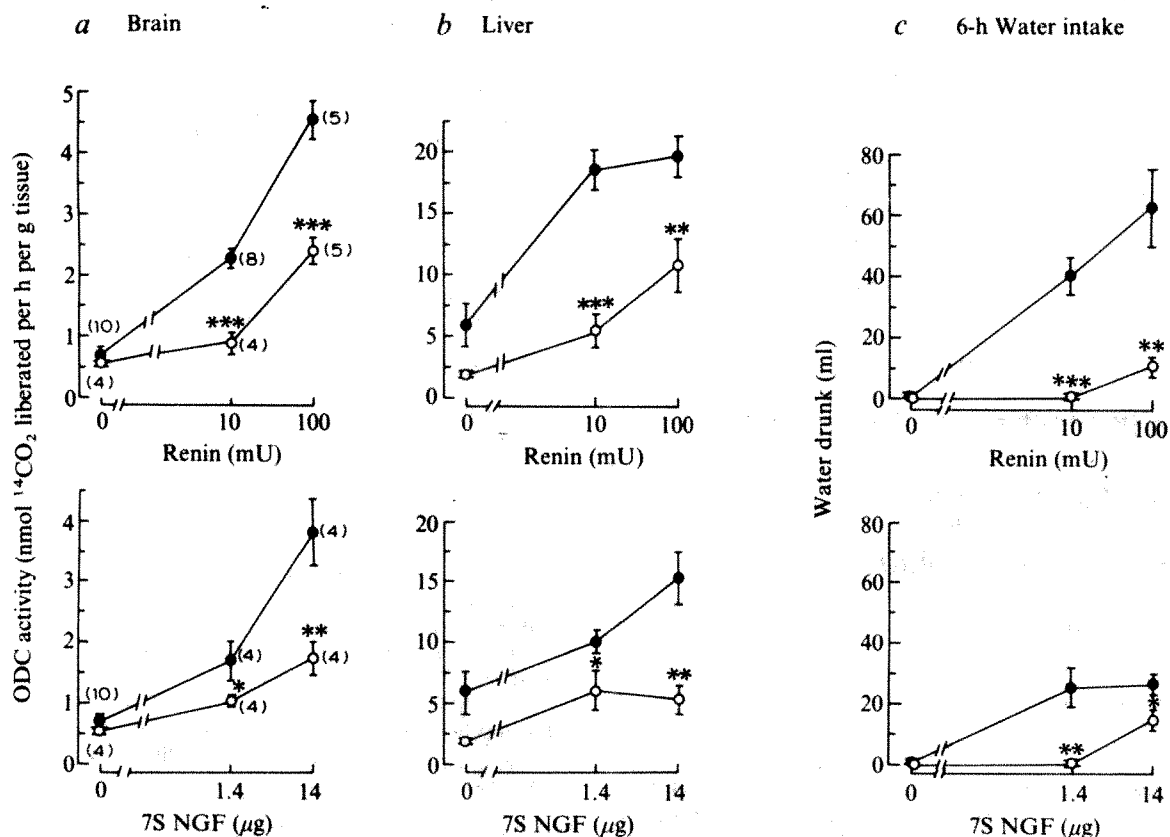
a Brain   *b* Liver   *c* 6-h Water intake


Fig. 3 The effect of a converting enzyme inhibitor (SQ 14225) on renin- and NGF-induced increases in ornithine decarboxylase activity in brain and liver and water intake in the same animals. Rats were given intraventricular injections[17] of either 7 μl or 0.9% NaCl or 7 μl 0.9% NaCl containing 35 μg SQ 14225, followed 2 min later by 5 μl injections of 0.9% NaCl, renin or 7S NGF. Six hours later, water intakes were recorded, the rats were killed and their brains and livers removed and frozen on solid CO_2. The activity of ornithine decarboxylase (ODC) in these tissues was measured essentially as described before[17,18] (mean ± s.e.m. is indicated with the number of animals in parentheses). The values for the control (●) and inhibitor-treated (○) animals were compared statistically as before. * $P < 0.05$; ** $P <$

A further question which has not been resolved is whether a renin-like enzyme should be regarded as an integral component of mouse submandibular gland NGF complexes. Isorenin and NGF are stored together in the same cells of the mouse submandibular gland[24], are closely associated physically[24], show the same sexual dimorphism and the same changes with age[25,26], and are both secreted in response to α-adrenergic stimulation[27,28].

In conclusion, experiments with inhibitors of the renin-angiotensin system demonstrate that several potent behavioural and biological effects of NGF preparations depend on the generation of AII by a renin-like enzyme in NGF. Therefore, unless renin-free preparations of NGF are used, antagonists of the renin-angiotensin system such as saralasin and SQ 14225 must be used in testing for putative NGF effects, particularly when a biological effect attributed to NGF is known to be produced by renin or AII.

We thank Miss Christine Narracott for technical assistance and the MRC for financial support. M.E.L. was supported by a Wellcome Research Fellowship from the Wellcome Trust.

Epidermal growth factor requirement for development of cultured mammary gland

Quentin J. Tonelli & Sam Sorof

The Institute for Cancer Research, Fox Chase Cancer Center, Philadelphia, Pennsylvania 19111

The mouse mammary gland in serum-free whole organ culture can be manipulated hormonally to undergo one complete physiological cycle consisting of lobuloalveolar development[1], functional differentiation and regression[2], mimicking processes that occur *in vivo*. A second cycle has not previously been achieved *in vitro*. The present study has identified a specific requirement for epidermal growth factor (EGF) in the morphological development of mammary lobuloalveoli, allowing two complete cycles of development and regression in culture.

Whole mammary glands of BALB/c mice were cultured for 9 days in serum-free development medium containing insulin (I), prolactin (P), aldosterone (A) and hydrocortisone (H) (Fig. 1 legend)[3,4]. At day 9, the glands contain fully developed lobuloalveoli[2,3] and casein[5]. When such glands are maintained in hormone-deficient regression medium (insulin as the only added hormone) for an additional 15 days (days 9–24), the lobuloalveoli involute (regress)[2,3]. Such regressed glands did not undergo a second development on return to the above IPAH medium (medium containing insulin, prolactin, aldosterone and hydrocortisone) for an additional 9 days (Fig. 1, Table 1). They were presumably depleted of necessary growth factor(s).
Fig. 1 Two cycles of development and regression of mouse mammary glands in whole organ culture. The serum-free culture system has been described[3,4,12]. Female BALB/c mice, 3–4 weeks old, were primed with 9 daily injections of β-oestradiol (1 μg) and progesterone (1 mg). On the day following the last injection, mice were killed and their entire second thoracic mammary glands were excised and floated on Dacron rafts. The serum-free development medium consisted of Waymouth MB752/1 medium (1 ml per gland) supplemented with $350\ \mu g\ ml^{-1}$ L-glutamine, $35\ \mu g\ ml^{-1}$ penicillin G, and $5\ \mu g\ ml^{-1}$ of each of the hormones, insulin (I), prolactin (P), aldosterone (A) and hydrocortisone (H). Medium was changed every 2 to 3 days. Glands cultured in the development medium for 9 days (days 0–9) underwent first lobuloalveolar development[1-3,12]. Exposure of these glands to regression medium containing insulin ($5\ \mu g\ ml^{-1}$) as the only added hormone for additional 15 days (days 9–24) caused first regression of the mammary lobuloalveoli[2,3,12]. Glands were then incubated in development medium with EGF for another 9 days (days 24–33), resulting in second development of the mammary glands. Second-developed mammary glands were then regressed in the regression medium for an additional 15 days (days 33-48). Glands were fixed, stained, coded[3] and evaluated as in Table 1.

We have found that the polypeptide, EGF, a purified mitogenic protein of molecular weight 6,100 (ref. 6), specifically induces a second development in previously regressed whole mammary glands. The presence of EGF in combination with IPAH for 9 days (days 24–33) elicited this effect in more than 71% of the glands in the absence of serum (Fig. 1, Table 1). The development was verified by microscopic examinations of the whole organ (Fig. 2) and at the cellular level. This positive response was in marked contrast to the refractoriness of the glands to the polypeptides, nerve growth factor, fibroblast growth factor, and multiplication stimulating activity factor, each in the presence of IPAH. Supplementations of IPAH with fetal bovine serum (FBS), growth hormone, β-oestradiol, and progesterone singly or in combinations were also ineffective. The addition of growth hormone to IPAH and EGF resulted in no additional development, and the combination of growth hormone, FBS and IPAH actually inhibited the second development-promoting activity of EGF.
Fig. 2 Second lobuloalveolar development of mouse mammary gland in whole organ culture. Entire mammary glands were cultured for 24 days according to the protocol described in Fig. 1 legend. Glands were cultured for an additional 9 days (days 24–33) in the IPAH medium with or without 10 nM EGF. Glands were then processed as described in Fig. 1 legend and Table 1. *a*, Whole mammary gland showing second-developed lobuloalveoli after incubation in the medium containing EGF. *b*, Control gland similarly incubated in the medium without EGF. The epithelial cells are primarily ductal, and alveoli are absent.
Fig. 3 ^{3}H-thymidine incorporation in mammary epithelial cell nuclei during second development of mouse mammary glands in whole organ culture. After first development (days 0–9) and regression (days 9–24), as in Fig. 1 legend, the mammary glands were placed in serum-free medium containing insulin, prolactin, aldosterone and hydrocortisone (5 μg ml⁻¹ each) in the presence (●) or absence (control, ○) of 10 nM EGF. The presence of mammary fat surrounding the epithelial cells within the fat pad apparently necessitated the uses of relatively high levels of radioactivity and long exposure time. Glands were pulsed for 1 h with 5 μCi ml⁻¹ ^{3}H-thymidine (128Ci mmol⁻¹; NEN) at the different times, and then were fixed[3]. Autoradiographs of 5-μm histological sections were prepared by dipping the slides in Kodak NTB-2 emulsion. The coated slides were placed in toluene with scintillator (4 g PPO, 0.05 g POPOP per litre), and exposed for 10 days in the dark at −60 °C. Slides were developed[21], stained with haemotoxylin and eosin, and mounted for examination. Epithelial cell nuclei with more than 5 silver grains were scored as positive. A minimum of 500 nuclei were counted from each section. Results from 4 sections are expressed as average numbers of labelled nuclei ± standard deviations (vertical limits).

The activity of EGF was concentration dependent. Significant activity was absent at 1 nM or less, but was maximal at 10 nM and 100 nM, inducing second development in 70 and 75% of the glands, respectively ($P < 0.0001$). The latter concentrations of EGF approximate those present in mammalian tissues[7].

The second development induced by EGF and IPAH apparently stimulated the mammary epithelial cells to undergo synthesis of DNA over the course of 1 week. As determined by ^{3}H-thymidine incorporated into cell nuclei, a peak of DNA synthesis occurred in 25% of the mammary epithelial cells at 8 h after addition of EGF, with perhaps a second peak at day 3, and a third at day 6 (Fig. 3). This periodicity is compatible with a cell generation of 3 days.

Glands that underwent second development in EGF (10 nM) and IPAH (each 5 μg ml⁻¹) regressed at the end of 15 days (days 33–48) in medium containing insulin as the only added hormone (regression medium) (Fig. 1). A third development was not induced in the presence of EGF and IPAH.

Table 1 Specific induction of second mammary development by epidermal growth factor in whole organ culture

Additions to IPAH	Concentration	No. of glands	>50% Alveoli developed	
			Glands	% Glands
None	—	26	2	8
EGF	10 nM	28	20	71*
NGF	10 ng ml⁻¹	28	4	14
FGF	10 ng ml⁻¹	26	1	4
MSA	10 ng ml⁻¹	28	3	11
FBS	10%	9	0	0
G	5 μg ml⁻¹	21	2	10
E + Prg	1 ng ml⁻¹, 1 μg ml⁻¹	34	2	6
EGF + G	10 nM, 5 μg ml⁻¹	16	8	50*
EGF + G + FBS	10 nM, 5 μg ml⁻¹, 10%	18	3	17

Mouse mammary glands in serum-free whole organ culture were induced to undergo first development (days 0–9) and then regression (days 9–24), as in the Fig. 1 legend. With the aim of achieving a second development, the fully regressed glands were incubated for another 9 days (days 24–33) in serum-free development medium containing IPAH (each at 5 μg ml⁻¹) and the listed additions. Epidermal growth factor (purified from male mouse submaxillary glands), nerve growth factor (NGF), fibroblast growth factor (FGF), multiplication stimulation activity factor (MSA) (all Collaborative Research), fetal bovine serum (FBS; Gibco), growth hormone (G; Miles), β-oestradiol and progesterone (E, Prg; Sigma) were present at the stated concentrations. At day 33, the organs were coded, fixed and stained[3]. The relative extents of development were scored on the basis of the percentage of developed lobuloalveoli in individual glands, 0 representing no development and 100% full development. The percents of the numbers of >50% developed glands are indicated.
* Significant second development according to Fisher's 2×2 exact test.

In contrast to its second development-promoting activity, EGF added alone or in combination with several steroid or polypeptide hormones induced little or no first development of alveoli. The hormones P, I, IA, IH, IAH, AH, each at 5 μg ml⁻¹, either alone or with EGF (10 nM), did not promote first development. However, the two combinations, IP with EGF, and PAH with EGF, did elicit moderate activities compared to IPAH without EGF (first development medium).

The polypeptide growth factor, EGF, may have a necessary and specific role in the physiological actions of the mammary gland. EGF acting with the hormones IPAH enables the mouse mammary gland to undergo a second development from the fully regressed state in serum-free culture. A stimulation of DNA synthesis seems to be involved. The requirement for EGF

is specific. The activity of EGF is maximal at physiological concentration (10 nM)[7]. Presumably endogenous stores of EGF operate in first development, as exogenous EGF does in second development. The mouse mammary gland can thus be manipulated to undergo two complete cycles of mammary gland development and regression in whole organ culture (Fig. 1).

EGF has been reported to induce mitogenesis[8-10], DNA synthesis[8-11] and RNA synthesis[8] in cultured fragments or dissociated cells of mammary glands. Starting with fragments of mammary glands already partly developed *in vivo* during pregnancy, additional development was induced in culture in response to EGF with insulin or hydrocortisone[8]. The present demonstration of the ability of EGF to promote a second development of mammary gland from the fully involuted state, permitting two cycles of development and regression *in vitro*, considerably extends knowledge of the importance of EGF in the regulation of mammary gland development.

Transformation of mouse mammary glands by chemical or carcinogens in whole organ culture is manifest as a persistance of developed lobuloalveoli in hormone-deficient medium (insulin as the only added hormone). The transformed glands, which are dysplastic, metaplastic[3,12] and oncogenic[14] have escaped from the growth controls normally imposed by prolactin and specific steroids[3,14]. The finding of an EGF role in mammary gland development and other observations[12,15-20] raise the question whether a deregulation of the EGF system may mediate the loss of controls of lobuloalveolar development that characterizes the mammary gland transformation by chemical carcinogens.

We thank Dr Wayne Ruppel for analysis of data, Dr R. Philip Custer for microscopy, Ms Gail Nussbaum for assistance and Dr Stanley Cohen for a gift of EGF. This work was supported in part by NIH grants CA-21522, CA-05945, CA-09035, CA-06927, RR-05539 and an appropriation from the Commonwealth of Pennsylvania.

Monkey pituitary oestrogen receptors and the biphasic action of oestradiol on gonadotropin secretion

Barbara Attardi, Julane Hotchkiss & Ernst Knobil

Department of Physiology, University of Pittsburgh, School of Medicine, Pittsburgh, Pennsylvania 15261

Evidence has been advanced in favour of the hypothesis that, in the rhesus monkey, the negative feedback as well as the stimulatory or so-called 'positive feedback' action of oestrogen on gonadotropin secretion is at the level of the pituitary gland[1-3]. The cellular basis for this biphasic action of oestrogen on the gonadotroph is not understood. In oestrogen target tissues the elicitation of physiological responses is generally associated with the binding of oestrogen to cytoplasmic receptor proteins which are subsequently translocated to the nucleus. Such receptors have been characterized in the anterior pituitary of the rat[4-6]. In the ovariectomized rhesus monkey infused with ^{3}H-oestradiol, autoradiography[7] and parallel cell fractionation[8] have demonstrated the accumulation of ^{3}H-oestradiol by the nuclei of a significant number of pituitary cells. We describe here some of the properties of these putative oestrogen receptors in the anterior pituitary of the monkey and observe that their distribution between cytoplasmic and nuclear compartments is constant in response to sustained elevations in serum oestrogen concentration which produce a biphasic pattern of circulating gonadotropins.

Ten ovariectomized rhesus monkeys which had responded to a trial injection of oestradiol benzoate (30 μg kg^{-1}) by manifesting a sharp decline in circulating LH followed by an LH surge were chosen for this study. Three animals received no further treatment and were kept as controls. Silastic capsules (4 cm long, 3.35 mm internal diameter, 4.65 mm external diameter, 7-9 per

animal) filled with crystalline 17β-oestradiol[9] were implanted subcutaneously in the other seven animals under ketamine hydrochloride anaesthesia. These implants produced constant peripheral oestradiol concentrations of 300-500 pg per ml serum. The oestradiol-treated animals were killed at the following times: 12-24 h (at the time of negative feedback inhibition of gonadotropin secretion), 44-48 h (at the height of the gonadotropin surge), and 96 h (after the gonadotropin surge). Each animal was anaesthetized with sodium pentobarbital (30 mg kg^{-1} intravenously), and cannulae were inserted into the carotid arteries. The calvarium was removed, the animal was swiftly decapitated, and the head was perfused with 400 ml ice-cold 0.9% NaCl to remove all traces of blood. The anterior pituitary was dissected free from the posterior pituitary gland, weighed, and processed for measurement of cytoplasmic or nuclear oestrogen receptor content (see figure legends for details).

Oestrogen receptors labelled with ^{3}H-oestradiol in the cytosol (soluble cytoplasmic fraction) from the anterior pituitary of one untreated control animal were found to sediment at approximately 7S in low ionic strength sucrose gradients (Fig. 1). The 7S peak was completely abolished by addition of a 100-fold excess of unlabelled diethylstilboestrol (DES). There was no indication of any contamination of the cytosol fraction by sex hormone binding globulin (SHBG) from the serum[10], as the serum [3]H-

Table 1 Pituitary gonadotropin content at various times after implantation of oestradiol-containing Silastic capsules in ovariectomized rhesus monkeys

		Pituitary gonadotropin content			
		LH		FSH	
Oestradiol treatment		(μg per gland)	(ng per mg wet weight)	(μg per gland)	(ng per mg wet weight)
Untreated	(2)	55.8 ± 0.7	900 ± 128	65.6 ± 11.4	1,033 ± 20
12-24 h E_2	(3)	85.2 ± 8.2	1,370 ± 27	137.3 ± 30.8	2,166 ± 375
44-48 h E_2	(3)	78.6 ± 31.3	1,349 ± 315	59.7 ± 19.6	1,052 ± 210
96 h E_2	(1)	26.9	782	<5.5	<100

Rhesus pituitary LH and FSH were measured by specific radioimmunoassays[22,23]. Number of determinations are in parentheses. Results are expressed as mean ±s.e.m.
Fig. 1 Sucrose gradient centrifugation of bound ³H-oestradiol in monkey serum or anterior pituitary cytosol. The anterior pituitary (62 mg) from an untreated ovariectomized monkey was homogenized in 20 vol TED (10 mM Tris-HCl, pH 7.4 at 25 °C, 1.5 mM EDTA, 1 mM dithiothreitol) as described previously[19]. Cytosol was prepared by centrifugation of the homogenate for 1 h at 189,000 g. Blood was collected from the same animal by femoral venipuncture and allowed to clot at 4 °C overnight. Serum was separated by centrifugation and diluted 1 : 10 with TED. Cytosol or diluted serum was incubated for 2 h at 0 °C with 10 nM [2,4,6,7-³H]17β-oestradiol (NEN, 102.0 Ci mmol⁻¹) in the absence (•) or presence (O) of 1 μM diethylstilboestrol (DES). Unbound ³H-oestradiol was removed from the cytosol fraction by treatment with dextran–charcoal (1/8 vol. 1.0% Dextran T 70, 10% Norit A in TED): samples were vortexed for 10 s, kept in ice for 20 min and centrifuged at 2,075 g for 15 min. Aliquots (0.25 ml) of serum or charcoal-treated cytosol incubates were layered on 5 to 20% linear sucrose gradients in TE buffer (10 mM Tris-HCl, pH 7.4 at 25 °C, 1.5 mM EDTA) and centrifuged in an SW 50.1 rotor at 215,000 g for 14.5 h (serum) or 16 h (cytosol). Eleven-drop fractions were collected directly into scintillation vials and counted. The arrow indicates the position of bacterial alkaline phosphatase added as an internal sedimentation marker (6.2S, see ref. 18). Direction of sedimentation was from right to left.

oestradiol-SHBG complex sedimented at 4S, and binding of ³H-oestradiol was unaffected by the presence of excess unlabelled DES (Fig. 1).

Scatchard analysis[11] of equilibrium binding data obtained by incubating aliquots of pituitary cytosol from two untreated ovariectomized animals with various concentrations of ³H-oestradiol (0.2–10 nM) in the absence or presence of 1 μM DES indicated the existence of a single class of high affinity, limited capacity binding sites (see Fig. 2 for a representative Scatchard plot). The dissociation constants (K_D's) obtained from these two experiments were 0.70 and 0.73 nM, and the concentrations of binding sites were 50 and 80 fmol per mg cytosol protein. Very low levels of oestrogen receptors were localized in the nuclear fraction (<0.3 fmol per pituitary) (Fig. 3).

Implantation of Silastic capsules containing oestradiol in ovariectomized monkeys led to depletion of cytoplasmic receptors to 10–20% of the levels found in untreated controls and concomitant accumulation of oestrogen receptors in the nucleus (Fig. 3). The concentrations of cytosol and nuclear receptors were constant during the period of oestrogen treatment. The loss of receptors from the cytoplasm could be accounted for by their presence in the nucleus. The total number of oestrogen receptors in the anterior pituitary were 63.4 (0 h), 62.3 (12–24 h), 64.5 (44–48 h) and 73.1 (96 h) fmol per pituitary when 5 nM ³H-oestradiol was used for cytosol binding and 72.7 (0 h), 61.4 (12–24 h), 63.6 (44–48 h) and 71.2 (96 h) fmol per pituitary when 10 nM ³H-oestradiol was used. As a result of this oestrogen stimulus, circulating luteinizing hormone (LH) and follicle stimulating hormone (FSH) levels declined at 12–24 h, peaked at approximately 44–48 h, and decreased again to low levels at 96 h (Fig. 3).

The time course of pituitary gonadotropin concentrations from these animals is shown in Table 1. Pituitary LH and FSH content both seemed to increase during the initial 24 h of oestradiol treatment and decrease again following the gonadotropin surge (96 h). A similar pattern of pituitary gonadotropin content is observed during the menstrual cycle of the rhesus monkey with an accumulation of LH and FSH before the midcycle gonadotropin surge followed by substantial depletion several days later[12]. These results are in agreement with the changes in pituitary LH content observed during the rat oestrous cycle[13] or during a simulated preovulatory LH surge in the rat[14]. We do not know at present whether the oestrogen-induced changes in pituitary gonadotropin content in the monkey are due to effects on synthesis, packaging, and/or release of LH and FSH; however, the effectiveness of oestradiol in regulating these processes is dependent on the prior exposure of the pituitary gland to permissive amounts of the hypothalamic gonadotropin-releasing hormone (GnRH)[15]. Note that depletion of pituitary gonadotropin stores with prolonged oestradiol treatment is presumably progressive: 2 years after placement of oestradiol implants in two intact female rhesus monkeys, pituitary LH and FSH were reduced to 2–3 ng per mg wet weight (W. D. Peckham, personal communication).

We have demonstrated that the anterior pituitary gland of the ovariectomized rhesus monkey contains cytoplasmic oestrogen receptors with properties similar to those found in rodent anterior pituitary tissue[4-6]. We assume that oestrogen receptors are present in rhesus pituitary gonadotrophs because of the profound effects of oestradiol on both the morphology[16] and secretory response of these cells. The presence of oestrogen receptors in other pituitary cell types cannot be excluded, however, as ³H-oestradiol has been localized by autoradiography in the nucleus of acidophils as well as basophils in the rhesus pituitary gland[7].

A sustained increment in circulating oestradiol leads to depletion of cytoplasmic receptors and their accumulation in the nucleus where they remain as long as serum oestradiol levels remain elevated. This same oestradiol stimulus results in a decline in gonadotropin secretion followed by a massive discharge of LH and FSH. Although it may not seem surprising that the interaction of oestradiol with the monkey pituitary conforms to the general model for oestrogen action in other target cells, the dynamics of oestrogen receptor populations have not been
Fig. 2 Binding of ³H-oestradiol (E_2) by monkey anterior pituitary cytosol as a function of ³H-oestradiol concentration (a) or as a Scatchard plot (b). A hemi-anterior pituitary (40 mg) from an ovariectomized untreated monkey was homogenized in 40 vol TED, and cytosol was prepared as described in Fig. 1 legend. Aliquots of cytosol were incubated with various concentrations of ³H-oestradiol (0.2—4.5 nM) in the absence or presence of 1 μM DES (total vol 100 μl). Incubation times, charcoal treatment to separate bound and unbound ³H-oestradiol, and radioactivity measurements are given in Fig. 3 legend. a, Specific binding (O) represents the difference between total binding measured in the absence of excess DES (•) and nonspecific binding (×) measured in its presence. Cytosol protein was determined by the method of Lowry et al.[18] using crystallized bovine serum albumin as standard.
Fig. 3 Content of specific oestrogen binding sites in cytosol and nuclear fractions from the anterior pituitary of ovariectomized rhesus monkeys and circulating gonadotropin concentrations as a function of time after the implantation of Silastic capsules containing crystalline 17β-oestradiol. Placement of implants and killing of animals are described in the text. Previously reported radioimmunoassays were used to measure serum oestradiol[20,21] (*a*), LH[22] and FSH[23] (*b*) in blood samples taken immediately before killing. Specific binding of ³H-oestradiol to cytoplasmic and nuclear receptors was determined by exchange assays (*c*). Data collected at times of negative feedback (12–24 h) or of positive feedback (44–48 h) have been plotted as the means of these times, 18 h and 46 h, respectively. Cytosol was prepared as described in Fig. 1 except that anterior pituitary tissue was homogenized in 40 vol TED. Cytosol fractions, treated with dextran-charcoal to remove any possible contaminating endogenous oestradiol, were incubated with saturating concentrations of ³H-oestradiol, 5 (●) or 10 (○) nM, in the absence or presence of 1 μM DES for 2 h at 0 °C (to fill any unoccupied receptor sites) followed by 16 h at 24 °C (to allow exchange of ³H-oestradiol with receptor sites filled with endogenous oestradiol)[24,25]. Total volume of incubation mixtures was 100 μl. After incubation, samples were placed in ice for 30 min and unbound ³H-oestradiol was removed by addition of 25 μl 5% Norit A–0.5% Dextran T70 as in Fig. 1. Aliquots (50 μl) of the charcoal-treated supernatants were counted in 5 ml Econofluor in a Packard scintillation spectrometer with an efficiency of 33%. The receptor measurements illustrated represent single determinations (46 h, 5 nM ³H-oestradiol; 18 h 10 nM ³H-oestradiol; 96 h, 5 and 10 nM ³H-oestradiol) or the mean±s.e.m. of 2 (18 h, 5 nM ³H-oestradiol; 46 h, 10 nM ³H-oestradiol) or 3 (0 h, 5 or 10 nM ³H-oestradiol) determinations. For measurement of nuclear receptors, anterior pituitary tissue was homogenized and nuclei isolated by the method of Zigmond and McEwen[26]. Nuclear oestrogen receptors were assayed as described by Roy and McEwen[27]. Briefly, receptors were salt-extracted from nuclei swollen in hypotonic buffer and incubated with 10 nM ³H-oestradiol, with or without 1 μM DES, for 16 h at 25 °C in a total volume of 125 μl. Aliquots (100 μl) of the incubation mixtures were applied to 6×50 mm Sephadex LH-20 columns equilibrated with TEK-0.4 (10 mM Tris-HCl, *p*H 7.4, 1.5 mM EDTA, 0.4 M KCl) and bound 3H-oestradiol was eluted into scintillation vials with 1 ml of the same buffer. Econofluor (10) was added, and after vigorous shaking, samples were counted as above with an efficiency of 38%. Nuclei were dissolved in 0.3 M KOH, and DNA contents were measured by the procedure of Burton[28]. Each data point (Δ) represents a single determination. The corresponding values in fmol per mg DNA are 329 (18 h), 383 (46 h), and 277 (96 h).

examined previously in conditions where this steroid exerts both an inhibitory and a stimulatory effect on the same process, presumably in the same cell type. Thus, any hypothesis for the mechanism of action of oestradiol in the sequential inhibition and stimulation of glycoprotein hormone secretion must appreciate that this biphasic effect of the steroid on the anterior pituitary is manifested in the face of an unchanging distribution of cytoplasmic and nuclear oestrogen receptors.

Glucocorticoids increase osteoblast-like bone cell response to 1,25(OH)₂D₃

Glenda L. Wong, Barbara P. Lukert & John S. Adams

Division of Metabolism, Endocrinology and Genetics, Department of Internal Medicine, University of Kansas Medical Center, Kansas City, Kansas 66103

Recent reports indicate that some hormones may regulate the binding of, and subsequent response to, other hormones by their target tissue[1-6]. The adrenal glucocorticoids are prominent among these modulating hormones[3-6]. Glucocorticoids have been shown to enhance bone cell sensitivity to parathyroid hormone (PTH)[6,7] *in vitro* and this in turn has permitted PTH-induced effects to be measured at physiological doses of PTH for the first time in isolated osteoblast-like (OB) and osteoclast-like (OC) cells. It is unknown whether these findings represent a specific interaction between glucocorticoids and PTH[6] or indicate a general role for glucocorticoids in the development and/or maintenance of bone cell differentiation, of which hormonal responsiveness would be one expression. In the event of a general glucocorticoid effect on cell differentiation, increased responsiveness to other bone resorbing hormones should also be observed. We have therefore examined whether glucocorticoids enhance the sensivity of bone cells to a steroid hormone, 1,25 dihydroxycholecalciferol (1,25(OH)₂D₃), and we report here that they do.

1,25(OH)$_2$D$_3$ can induce resorption of bone *in vivo*[8-10] and *in vitro*[11]. The biochemical changes induced by 1,25(OH)$_2$D$_3$ are very similar to those initiated by PTH—in both cases bone mineral and organic matrix loss is observed. PTH also stimulates hyaluronic acid synthesis[12,13] and lysosomal enzyme release[14,15] and inhibits collagen formation[16,17], alkaline phosphatase activity[18] and citrate decarboxylation[19]. Some of these metabolic events that accompany PTH-induced bone resorption have been reproduced in OC or OB bone cells exposed to pharmacological doses of 1,25(OH)$_2$D$_3$ (ref. 20). However, physiological doses of 1,25(OH)$_2$D$_3$ were without effect in these cells.

In previous studies low doses of glucocorticoids decreased basal osteoclastic but not osteoblastic activities. As a result the major enhancement of PTH responsiveness by glucocorticoids occurred in OB cells[7]. For this reason, these studies on the relationship between glucocorticoids and 1,25(OH)$_2$D$_3$ were carried out on OB bone cells. Inhibition of OB cell citrate decarboxylation by a submaximal dose of 1,25(OH)$_2$D$_3$ (100 pg ml^{-1}) was measured alone or in combination with various doses of glucocorticoids (Fig. 1a). At prednisolone levels below 10^{-10} M the inhibition of citrate decarboxylation by 1,25(OH)$_2$D$_3$ was unchanged. However, at 10^{-9}–10^{-7} M prednisolone, the decrease in citrate decarboxylation due to 1,25(OH)$_2$D$_3$ was greater than in cells not treated with glucocorticoid. Prednisolone enhancement of the effects of 1,25(OH)$_2$D$_3$ resulted from both a decrease in the absolute amount of citrate decarboxylated in the presence of 1,25(OH)$_2$D$_3$ and a small increase in basal citrate decarboxylation. To compare the relative enhancement by different doses of prednisolone the inhibition of citrate decarboxylation by 1,25(OH)$_2$D$_3$ is further expressed as a percentage of the appropriate glucocorticoid-treated control (Fig. 1b). Maximum potentiation of 1,25(OH)$_2$D$_3$ action was seen with 10^{-9} and 10^{-8} M prednisolone.

OB cell response to various doses of 1,25(OH)$_2$D$_3$ was measured in the absence or presence of a maximally effective dose of prednisolone (Fig. 2). The dose–response curve for 1,25(OH)$_2$D$_3$ became shifted to the left in the presence of 10^{-9} M prednisolone and 2–10-fold lower doses of 1,25(OH)$_2$D$_3$ were required to bring about an established degree of inhibition of citrate decarboxylation. Addition of 10^{-9} M prednisolone to the culture medium of OB cells permitted levels of 1,25(OH)$_2$D$_3$ as low as 5–25 pg ml^{-1} (amounts well within normal circulating levels) to be assayed for the first time in this *in vitro* cell culture system. Note that although the absolute sensitivity of the isolated OB cells to
Fig. 1 Effect of various doses of glucocorticoid on OB bone cell response to 1,25(OH)$_2$D$_3$. Primary cultures of OB bone cells were prepared as previously described[24], subdivided after 5 d and inoculated into glass test tubes (1.0 × 10^5 cells per tube) containing 1.0 ml (MEM) and 10% fetal calf serum. *a*, Cells were cultured with the indicated doses of prednisolone in the absence (open bars) or presence (closed bars) of 1,25(OH)$_2$D$_3$ (100 pg ml^{-1}). After 48 h, citrate decarboxylation was measured by the addition of [6-^{14}C]citrate (0.2 μCi ml^{-1}) for 2 h. ^{14}CO$_2$ was trapped on filter paper fans saturated with Hyamine ×10 as previously described[19,25]. *b*, Results are expressed as the per cent inhibition seen when 1,25(OH)$_2$D$_3$-treated cultures were compared with the appropriate prednisolone-treated control. These values represent the average of four determinations ±s.d., and these experiments were performed five times, with similar results. *P<0.005; **P<0.002; ***P<0.05.

1,25(OH)$_2$D$_3$ varied from preparation to preparation, the relative increased sensitivity in the presence of prednisolone was always maintained.

Increased sensitivity to 1,25(OH)$_2$D$_3$ could also be demonstrated when OB cell collagen synthesis was measured in prednisolone-treated cells exposed to 1,25(OH)$_2$D$_3$ (Table 1). Inhibition of collagen synthesis by 1,25(OH)$_2$D$_3$ increased from

Table 1 Effects of prednisolone and 1,25(OH)$_2$D$_3$ on collagen synthesis by OB bone cells

	Collagen (^{3}H-proline d.p.m. per 10 cells)	Non-collagen protein	% Decrease	% Total protein*
Control	5,500 ± 300	6,200 ± 360	—	13.0
Control + 1,25(OH)$_2$D$_3$	3,885 ± 350‡	6,000 ± 450	29	10.0
10^{-4} M Prednisolone	3,930 ± 400	5,300 ± 400	—	11.0

10^{-10} M Prednisolone	5,000 ± 400	6,200 ± 350	—	13.0
10^{-10} M Prednisolone + 1,25(OH)$_2$D$_3$	3,800 ± 250‡	5,650 ± 430	24	10.0

OB cells were cultured in the presence of 10^{-10}–10^{-4} M prednisolone alone, or in combination with 1,25(OH)$_2$D$_3$ (125 pg ml^{-1}). After 48 h the growth medium was removed, and the cells were further cultured in minimal essential medin containing 1.0 μCi ml^{-1} L-[2,3-^{3}H]proline (50 Ci mmol^{-1}) for 24 h. The media and the cells were precipitated *in situ* with 5% trichloroacetic acid (TCA). The precipitate was centrifuged and washed 4 times over a 24-h period with 12 ml ice-cold 5% TCA. The radioactivity rendered acid soluble by heating the cell pellets at 90 °C for 45 min in 1 ml 5% TCA was used as a measure of collagen ; Alternatively, the cell layer collagen was rendered acid soluble by digestion with purified bacterial collagenase. The acid-insoluble radioactivity remaining after these procedures (non-collagenous protein) was dissolved by heating at 60 °C for 30 min in 0.5 ml 0.2 M NaOH. Each value represents the mean of triplicate determinations ±s.d.
* Corrected for relative proline enrichment in collagen by a factor of 5.8.
† P<0.005. ‡ P<0.05.

29% in the absence of glucocorticoid to 36% at 10^{-6} M prednisolone, and reached a maximum at 44% at 10^{-8} M prednisolone; no enhancement was seen at 10^{-10} M prednisolone. Glucocorticoid amplifications of the effects of $1,25(OH)_2D_3$ on collagen and citrate decarboxylation thus occurred over a similar dose range. The additional decrease in collagen formation seen with $1,25(OH)_2D_3$ acting in the presence of prednisolone was specific as there was no corresponding change induced in the synthesis of non-collagenous protein.

The molecular basis for glucocorticoid amplification of $1,25(OH)_2D_3$ effects remains to be established. $1,25(OH)_2D_3$ interacts with target cells by binding to high affinity cytosolic receptors. Such receptors have been identified in fetal rat calvaria[21] and it was recently reported that glucocorticoids retard the turnover rate of $1,25(OH)_2D_3$ receptors in bone tissue in culture[22].

In the following experiments, the ability of primary cultures of OB cells to accumulate ^{3}H-labelled $1,25(OH)_2D_3$ was measured after growth in the presence or absence of glucocorticoids. Figure 3a demonstrates that after exposure to 10^{-9} or 10^{-7} M but not to 10^{-5} M prednisolone, OB cells showed a greater uptake of ^{3}H-$1,25(OH)_2D_3$ than untreated controls, with 10^{-9} M > 10^{-7} M > 10^{-5} M. At 10^{-9} M and 10^{-7} M glucocorticoid the uptake per cell of ^{3}H-$1,25(OH)_2D_3$ was increased ~60% and 40%, respectively, whereas no increase was seen at 10^{-5} M. The increase in cellular uptake of ^{3}H-$1,25(OH)_2D_3$ thus coincided with the prednisolone dose curve for enhancement of the biological effects of $1,25(OH)_2D_3$ in OB cells.

The specificity of OB cell uptake of ^{3}H-$1,25(OH)_2D_3$ was measured by competition with unlabelled $1,25(OH)_2D_3$. The addition of unlabelled $1,25(OH)_2D_3$ to the medium at the time of exposure to ^{3}H-$1,25(OH)_2D_3$ led to a decrease in the radioactivity ultimately recovered with the cells. Addition of 0.1, 1.0 or 10.0 ng ml^{-1} unlabelled $1,25(OH)_2D_3$ resulted in a decrease of 27%, 50% and 72%, respectively (Fig. 3b). Approximately 17% of the cell-associated radioactivity could not be displaced by $1,25(OH)_2D_3$ levels as high as 1,000 ng ml^{-1}, and must, therefore, be regarded as nonspecific binding. By comparison, even 10 ng ml^{-1} $24,25(OH)_2D_3$ reduced cell-associated radioactivity by <20% (Fig. 3c). $25(OH)_2D_3$ at 10 ng ml^{-1} also reduced cell-associated radioactivity by <20% (results not shown).

These results show that OB bone cells accumulate increased amounts of ^{3}H-$1,25(OH)_2D_3$ after exposure to low physiological doses of glucocorticoids. Increased accumulation of ^{3}H-$1,25(OH)_2D_3$ by glucocorticoid-treated cells could be due to a

Fig. 3 Effects of prednisolone on the uptake of ^{3}H-$1,25(OH)_2D_3$ by OB cells. Primary cultures of $2.0-2.5 \times 10^6$ cells were exposed to 0, 10^{-5}, 10^{-7} or 10^{-9} M prednisolone for 48 h. Cell monolayers were then rinsed two times with MEM. a, Cells were further incubated with 3 ml MEM containing 30,000 pm ml^{-1} of $[23,24(n)$-^{3}H$]1\alpha,25(OH)_2D_3$ (94 Ci mmol^{-1}) (Amersham). After 60 min at 37 °C the medium was aspirated off, and the monolayers were rinsed in phosphate-buffered saline (PBS). The cells were recovered from the tissue culture flask by suspension in calcium–magnesium-free Tyrode's solution containing 0.005 M EDTA, pH 7.0 (EDTA/Tyrodes). Cells were pelleted by centrifugation at 600g for 2 min, then rinsed five times with 10 ml PBS. (At this stage the total radioactivity in the wash was <20% of that associated with the cells.) The cell pellet was then resuspended in 2 ml EDTA/Tyrodes to obtain single cells and 0.025 ml was removed for cell counting in a haemcytometer. The remaining cells were collected on a Millipore filter, which was further rinsed with 10 ml PBS, dissolved in methyl Cellosolve, mixed with aqueous scintillant, and counted in a Searle liquid scintillation counter. b, c, ^{3}H-$1,25(OH)_2D_3$ uptake (by OB cells) was measured as described above except either $1,25(OH)_2D_3$ (b) or $24,25(OH)_2D_3$ (c) was added to the cells at the same time as ^{3}H-$1,25(OH)_2D_3$. These measurements represent the average of three determinations ±s.d. and these experiments were performed four times.

Fig. 2 Amplification of bone cell response to $1,25(OH)_2D_3$ by glucocorticoid. Subcultured OB bone cells were grown in various concentrations of $1,25(OH)_2D_3$ alone (○) or further supplemented with 10^{-9} M prednisolone (●). After 48 h citrate decarboxylation was measured as the amount of $^{14}CO_2$ evolved from [6-^{14}C]citrate (0.2 μCi ml^{-1}) added to each tube for the final 2 h. Results are expressed as the per cent decrease obtained when $1,25(OH)_2D_3$-treated cultures were compared with the appropriate control and each point represents the average of four replicate samples ±s.d. These experiments were performed six times.

variety of reasons including: (1) an increase in total cell protein; (2) increased cell permeability to steroids including $1,25(OH)_2D_3$; or (3) a specific increase in the numbers or affinity of the receptors for $1,25(OH)_2D_3$. As incorporation of ^{3}H-proline (Table 1) and ^{3}H-leucine[7] into acid precipitable radioactivity was not increased in cells cultured in glucocorticoids, the first possibility seems unlikely. Furthermore, the relative inability of $24,25(OH)_2D_3$ and $25(OH)_2D_3$ to compete with ^{3}H-$1,25(OH)_2D_3$ and the ability of $1,25(OH)_2D_3$ to decrease cell-associated ^{3}H-$1,25(OH)_2D_3$ suggest that the increased accumulation of ^{3}H-$1,25(OH)_2D_3$ by glucocorticoid-treated cells was not due to a general increase in cell permeability, but rather was a phenomenon specific to $1,25(OH)_2D_3$.

The enhancement of $1,25(OH)_2D_3$ effects on OB bone cells by glucocorticoids is of interest from the molecular as well as physiological point of view. These results imply that glucocorticoids *in vivo* permit bone tissue to respond to small increases in $1,25(OH)_2D_3$. In addition, the permissive role of glucocorticoids for $1,25(OH)_2D_3$ parallels that previously described for PTH although the mechanism of action of these two hormones differ at the onset. Glucocorticoids must therefore control a complex set of cellular reactions which can result in amplification of response to at least two classes of bone resorbing hormones, one of which activates adenylate cyclase via cell surface receptors,

the other of which binds to intracellular cytosolic receptors. If hormone sensitivity can be used as a marker for cell specialisation, then glucocorticoids can be further said to enhance the expression of the differentiated phenotype in bone cells, and *in vivo* may exert some control on bone cell development and maintenance.

Allotype-linked genetic control of a polymorphic V_H framework framework determinant on mouse T-helper cell receptors

Yinon Ben Neriah, David Givol & P. Lonai

Department of Chemical Immunology, The Weizmann Institute of Science, Rehovot, Israel

Markus M. Simon & Klaus Eichmann

Institute for Immunology and Genetics, Deutsches Krebsforschungszentrum, Heidelberg, FRG

The immune system confronts antigens through the variable domains of antigen receptors on lymphocytes. The biochemistry of these antigen receptors is fundamental to the understanding of the immune system. Whilst B cells use immunoglobulins (Ig) as antigen receptors, T cells use unknown molecules which appear to differ from Ig except for the shared variable region of the Ig heavy chain (V_H). The notion that T-cell receptors consist, at least in part, of immunoglobulin V_H regions stems largely from experiments using anti-idiotypic antibodies[1-3]. Much serological and genetic evidence has meanwhile accumulated suggesting that V_H associated idiotypic determinants are shared between Ig molecules and the antigen receptors of certain classes of T cells including helper cells, cells proliferating on mixed lymphocyte reaction delayed type hypersensitive reactive cells, and cytotoxic T cells[4-7]. This pertains to structural elements associated with hypervariable portions of V_H, but data on framework elements of V_H regions of T cells are scarce[8,9]. We have previously reported that mouse T-cell receptors react with a rabbit antibody to the V_H fragment of MOPC 315 (anti-V_H)[10-12]. The V_H framework determinants appeared polymorphic in that the T-helper cells as well as the immunoglobulin heavy (H) chains of a variety of mouse strains reacted equally well, except in the case of strain AKR[12,13]. We report here the genetic control of the V_H framework determinant whose expression through T-helper cells seems to be governed by at least one gene linked to the Igh allotype linkage group. Thus, this V_H framework determinant behaves like the rabbit V_H region allotypes which are expressed on both immunoglobulin H chains and T-cell receptors[8,9]. These data suggest the expression of entire V_H regions in T-cell antigen receptors[1-3].

The analysis of the reactivity of anti-V_H with T-helper cells involved the *in vitro* responses of spleen cells from mice previously immunized with streptococcus A (ref. 14) to trinitrophenylated group A streptococci (TNP-Strep.A). This T-helper cell-dependent response is inhibited by addition of anti-

V_H to the culture, whereas inhibition of the T-helper cell-independent response to TNP-Ficoll requires at least a 50-fold greater concentration of anti-V_H (ref. 12). Failure of anti-V_H to react with immunoglobulin molecules and B cells has been reported previously[10,12,13,15], suggesting that the inhibition of the TNP-plaque-forming cell (PFC) response to TNP-Strep. A reflects exclusively the inhibition of T-helper cells by anti-V_H (ref. 12).

Preliminary experiments showed that the responses of cells from strains A/J, DBA/2 and BALB/c were strongly inhibited by anti-V_H, whereas those from strain AKR were not (ref. 12, and unpublished data). We therefore crossed strain AKR with DBA/2 and backcrossed the F_1 to AKR. Figure 1 shows the effect of anti-V_H on the *in vitro* responses of spleen cells from mice resulting from this cross to TNP-Strep. A. It is clear that the capacity of cells to be inhibited by anti-V_H is inherited in a dominant fashion. In the backcross, no clear segregation into positive and negative groups can be seen. However, because of the gap between 31% and 38% inhibition, and because all F_1 mice were inhibited more than 38%, we divided the backcross mice into two groups: one group of 15 showed inhibition similar to that of F_1 mice; the other group of 9 were less strongly

inhibited. These groups were then analysed with respect to seven different genetic markers—H–2, Thy 1, Lyt 1, Lyt 3, sex, coat colour, allotype—segregating in this cross. Table 1 shows that there is no association with any of these markers, except for the Igh allotype with which a significant association is observed. This suggested that this allotype had an important role in the genetic control of V_H expression in T-helper cells.

From these experiments the question arose as to whether the expression of V_H on T cells is exclusively by the Igh allotype controlled or, as would seem more likely from the data in Fig. 1 and Table 1, whether it is controlled by additional genetic factors. We investigated this by improving the quality of the T-helper cell inhibition assay using partially helper cell-depleted spleen cells as responders. This was done by mixing 20% of untreated spleen cells with 80% anti-Thy-1.1 and complement-treated spleen cells of each individual mouse. Because of the limitation of T-cell help in such cultures, smaller quantities of anti-V_H can be used for inhibition, so that the possibility of nonspecific inhibition or of B-cell inhibition is minimized[12].

An analysis of AKR, DBA/2 and (AKR×DBA/2)F₁ mice by this improved procedure again clearly reveals the genetic polymorphism and dominant inheritance of the V_H determinant

(Table 2). Analysis of an additional 20 (AKR×DBA/2)×AKR backcross mice by this typing procedure now reveals a clear segregation into a positive and a negative group and unequivocal linkage to the Igh allotype (Table 3, Fig. 2).

These data support our previous observation that T-helper cells express framework portions of immunoglobulin V_H regions[11,12]. The significance of these results is that the genetic evidence is independent of the serological data[11,12,15], and that both lines of evidence point to the same conclusion. The lack of an influence of H-2 observed in these data is not inconsistent with our previous report showing that an idiotype of alloreactive T-cells is controlled by the Igh allotype as well as by H-2 (ref. 6). One critical difference is that, whereas in the present work an antiserum to immunoglobulin V_H determinants was used, the previous report used an antiserum against T-cell receptors which presumably detects unique determinants on T-cell receptors in addition to those shared with immunoglobulin H chains. The
Fig. 1 Inhibition of the TNP-PFC responses of 10^6 spleen cells from individual mice immunized 3–6 weeks previously with 4×10^9 Strep.A particles, cultured for 4 days in 100 μl Click's medium in microwells together with TNP-Strep.A[12]. Sixteen identical microcultures were run of each mouse, eight of which contained 20 μg anti-V_H antibody. Each point represents the result of a single mouse and gives the inhibition of the mean PFC response of the cultures containing anti-V_H as a percentage of that of cultures without anti-V_H. Absolute PFC responses were of the order of those shown in Tables 2 and 3.

Fig. 2 Graphic representation of the data from Tables 2 and 3. The experiment was done as represented in Fig. 1, with the following modifications: cultures contained 3×10^6 cells in 300 µl medium 20% of which were spleen cells, 80% of which were previously treated with a Thy-1.1 and rabbit complement. Eight identical cultures of each mouse were run, four of which contained 5 µg anti-V_H antibody.

other difference that may be critical is that in our previous report the T-cell receptors investigated were specific for major histocompatibility complex antigens[6].

It has come to our attention that other helper cell systems are not inhibited by anti-V_H (A. Coutinho, personal communication). We conclude that anti-V_H may react with only a

proportion of T-helper cell receptors, either by masking of the V_H determinant on some T-cells by combination of V_H with other structural elements in analogy to its masking by light chains on antibodies[13], or by preference of anti-V_H for what may reflect V_H subgroups on T cells. The partial inhibition and the pronounced individual variability seen in many of our experiments[12] may be explained by subgroup preferences of the anti-V_H antibody and variability in the proportions of such V_H subgroups activated in different individuals and in response to different antigens. Taken together, we feel that antibodies to V_H framework determinants may become important in the analysis of T-cell receptors, particularly as far as their biochemical analysis is concerned.

We thank Ms I. Falk and Ms Tova Volberg for technical assistance. This work was supported by a grant for Cooperative Cancer Research between Israel and West Germany.

Murine leukaemogenesis: monoclonal antibodies to T-cell determinants arrest T-lymphoma cell proliferation

Michael S. McGrath, Eric Pillemer & Irving L. Weissman

Laboratory of Experimental Oncology, Department of Pathology, Stanford University, Stanford, California 94305

We have proposed a receptor-mediated leukaemogenesis hypothesis wherein T lymphomas would be clones of T cells bearing mitogen-linked surface receptors specific for the envelope determinants of the inducing MuLV[1–3]. A prediction of the hypothesis is that T-lymphoma proliferation is dependent on continued presentation of MuLV envelope determinants to these cell-surface receptors, and that substances which interfere with receptor–virus interactions should inhibit T-lymphoma proliferation. Rat monoclonal antibodies were raised to the AKR mouse T lymphoma KKT-2, and these antibodies were screened independently for blockade of virus-binding and for cytostatic activity on KKT-2 cells. We report here that those monoclonal antibodies which block virus binding inhibit growth of KKT-2 cells in vitro, whereas monoclonal antibodies which bind to these cells but do not block virus binding are not cytostatic. Three of the four cytostatic antibodies detect determinants on the Thy-1 molecule, while none of the other (noncytostatic) antibodies detect Thy-1. Antibody inhibition of KKT-2 cell growth is precluded by saturation of KKT-2 virus receptors with the inducing leukaemia virus.

Spleen cells from Fisher rats immunized with KKT-2 lymphoma cells were fused with the hypoxanthine, aminopterin and thymidine (HAT) sensitive myeloma NS-1 (ref. 4), and antibody-forming cell hybrids were grown and cloned by limiting dilution. The antibodies used in this study and their characteristics are shown in Table 1. A complete characterization of these monoclonal antibodies, the molecules recognized, and

functions on normal cells will be described elsewhere (E. Pillemer *et al.*, in preparation).

To test the possible growth inhibitory function of these various monoclonal antibodies, we added them to logarithmically growing KKT-2 cells *in vitro*. As demonstrated in Fig. 1, exposure to dilutions of antibodies produced by clones 31-11, 31-8, 42-21 and 19XE5 resulted in greatly diminished thymidine uptake, whereas antibodies from clones 43-17, 43-13,
Fig. 1 Lymphoma cell growth inhibition assay. KKT-2 lymphoma cells were pelleted from subconfluent cultures and resuspended in serum-free growth medium (MEM, GIBCO) for 2 h at 37 °C at a density of 10^5 cells ml^{-1}. After repelleting, the cells were resuspended in cold tissue culture medium (MEM, 10% FCS) at a density of 2×10^4 cells ml^{-1}. 5×10^4 Cells (2.5 ml) were placed in the bottom of 25-cm^2 Corning tissue culture flasks and serial dilutions of monoclonal antibodies were added. After growing for 14 h at 37 °C, 0.1 ml of medium containing 10 µCi ^{3}H-thymidine (NEN) was added to each culture for 2 h. Labelled cells were washed, 5% TCA precipitated, and per cent growth inhibition was calculated using cells without antibody as equal to 100% growth. KKT-2 cells were tested for growth inhibition with: *a*, anti-Thy 1 (19XE5, 30-H12, 31-11, 42-21); *b*, anti-MuLV (16B7, 9E8); and *c*, anti-cell surface antibodies (31-8, 43-17, 43-13). Data represent averages of three experiments. Similar data result when 19XE5 and 16B7 antibodies purified from hybridoma supernatants (by protein A columns)[15] were utilized. □, Represents 1:12 dilutions of non-inhibitory antibodies, 43-13, 43-17, 16B7 and 30-H12.

Monoclonal antibodies (31-8, 31-11, 43-13, 43-17 and 42-21) were prepared by a modification of the technique of Galfré *et al.*[4]. Briefly, Fisher rats were immunized with KKT-2 lymphoma cells; three days following the final intravenous injection, the spleen (approximately 2 × 10⁸ cells) was fused with 10⁷ NS-1 myeloma cells using 38% polyethylene glycol-1540. Hybrids were grown initially in super HAT medium[12] in 24-well plates (Falcon 3008). Supernatants were tested for binding to a panel of tumour cells, normal lymphoid cells and purified virus using a conventional radioimmunoassay (RIA) with a ¹²⁵I-labelled rabbit anti-rat second stage as the detecting reagent. MCF-247 and KKT-2-SL viruses were prepared by Sepharose 4B chromatography[13]. Molecular weight determinations were performed as previously described[5]. Specificities for most of the antibodies have been described previously; work is continuing to characterize molecules recognized by the 43-13, 43-17 and 42-21 monoclonals. Clone 31-8 has been lost. Identity of tumour cell lines: (1) KKT-2 is a spontaneous AKR/J lymphoma; (3) L691/K is the L691 lymphoma super-infected with the KKT-2-SL virus[5]. +, Relative level of binding as determined by RIA; –, indicates that binding was at the level of background obtained when using the second stage reagent alone. Rat monoclonal 30-H12 was provided by J. Ledbetter[14]. Mouse monoclonals 9E8, 19XE5 and 16B7 were provided by R. Nowinski[15].

16B7, 9E8 and 30-H12 were without effect on DNA synthesis. Growth inhibitory antibodies block DNA synthesis significantly at concentrations to 1:10,000, while cell binding, non-inhibitory antibodies are ineffective, even at concentrations approaching 1:10. This inhibition was not related to antigen mobility as the inhibitory antibodies show different patching and capping activity in the presence of second stage antibodies; 19XE5 and 42-21 caused rapid membrane capping, 31-8 intermediate capping activity, and 31-11 caps very slowly and incompletely (data not shown). The inhibition was extremely cell density dependent, and was optimal with exponentially dividing cells at less than 2 × 10⁴ cells per ml. At 2 × 10⁵ cells per ml, even 1:10 dilutions of 31-11 were not inhibitory.

Figure 2 shows that KKT-2 cell growth inhibition is directly related to the level of cell-surface antibody bound and degree of interference with murine leukaemia virus (MuLV) binding. Growth inhibitory levels of 31-11 and 42-21 (>50% saturation) significantly blocked MuLV binding whereas the non-inhibitory 43-17 antibody did not.

The effect of growth inhibitory antibodies seems to be most active in cell-cycle phase G_1. We have previously shown that after exposure to 31-11 antibody, KKT-2 cells show a linear fall to background in their ability to synthesize DNA within 8 h with a shift in DNA content from 4n towards 2n copies within 20 h. This corresponds to a shift in size from large lymphoblastic to small G_0-type lymphoid cells within 24 h, culminating in non-complement mediated cell death within 48 h[5].

If growth inhibition by particular monoclonal antibodies is mediated by steric or direct blockade of receptor–viral envelope interactions, then preincubation of lymphoma cells with their inducing retrovirus ought to fill such receptors, preventing antibody-induced growth inhibition. To test this possibility, we preincubated KKT-2 lymphoma cells with saturating concentrations of their own endogenously produced SL retroviruses, or with various viruses closely or more distantly related (as defined by host of origin[6], shared and distinct antigenic determinants[7], and cell-binding specificity[3,8]). We then added monoclonal antibodies to these mixtures at growth inhibiting concentrations. The results, shown in Table 2A, were striking: only the endogenously produced retrovirus (KKT-2-SL) prevented antibody-induced growth inhibition of KKT-2 cells. Table 2B demonstrates that this inhibition is not secondary to a direct interaction of antibody and virus, as preadsorption of limiting concentrations of antibody with a great excess of virus does not prevent growth inhibition. We have demonstrated elsewhere that prebinding of KKT-2 cells with saturating levels of virus does not alter the amount of 31-8 or 31-11 antibodies bound to these cells[5].

To test whether live viruses are necessary for continued cell growth in the presence of inhibitory antibodies, we preirradiated

KKT-2-SL virus with doses of UV known to inactivate >99.99% viral replicating and infectious activity[9] before prebinding. This radiation dose did not affect the ability of these virions to prevent growth inhibition by monoclonal antibody (Table 2C).

These experiments demonstrate that T-lymphoma cells, like T lymphocytes, are under cell-surface regulation for stimulation and cessation of DNA synthesis. It is likely, therefore, that leukaemogenic retroviral oncogene action involves stimulation of cell-surface mitogen receptors, alone or in combination with other intracellular signals. These latter signals may also be under viral genetic control, either by direct expression of viral genes or by selective activation of host genes. In this view cell-surface stimulation would be necessary, but not sufficient for lymphoma cell proliferation. As a corollary, lymphoma cell growth

Table 2 Inhibition of antibody-induced KKT-2 cell growth arrest

D Control cells without inhibitory antibody addition	100	100

The standard KKT-2 cell growth inhibition assay as outlined in Fig. 1 legend was carried out with 31-11 and 31-8 antibodies at a 1:250 dilution on 5 × 10⁴ KKT-2 cells after preincubation with purified retroviruses. *A*, 0.01 A_{260} unit of Sepharose-4B purified virus[13] in 0.3 ml phosphate buffered saline (PBS) was incubated with KKT-2 cells for 60 min. at room temperature before addition of inhibitory antibodies. This amount of virus represents a receptor saturation level as previously determined[8]. The origin of each retrovirus population has also been previously described[3,8]. *B*, One A_{260} unit of Sepharose purified KKT-2-SL, L691/M and BL/Ka[B] virus in PBS was incubated with 31-11 and 31-8 antibodies at a 1:2.5 antibody dilution for 60 min at room temperature with PBS control absorbed samples. The samples were spun at 100,000g for 120 min to pellet virus, and the absorbed antibodies were tested in the standard KKT-2 cell growth inhibition assay (Fig. 1). All inhibitions were carried out at a 1:250 final antibody dilution. *C*, Sepharose-4B purified KKT-2-SL virus was UV inactivated and used to inhibit antibody induced KKT-2 cell growth inhibition as in *A*. Virus (5 ml) in PBS (1 A_{260}unit ml⁻¹) was irradiated for 145 s at 4,000 erg mm⁻² before use. *D*, Control growth inhibition of KKT-2 cells in the absence of inhibitory antibodies.
Fig. 2 Effect of serial dilutions of monoclonal antibodies prebound to KKT-2 cells on growth inhibition and MCF-247 virus binding. 10^6 KKT-2 cells were suspended at 2×10^4 cells per ml in serial dilutions of monoclonal antibody supernatants: *a*, 31-11; *b*, 42-21; *c*, 43-17, for 1 h at 0 °C before washing through neat fetal calf serum. Fluoresceinated MCF-247 binding and detection of cell-surface antibody by fluorescence-activated cell sorter analysis was carried out on 4.75×10^5 cells each as previously described[3]. 5×10^4 cells from each point were suspended in 2.5 ml of MEM/10% FCS and growth inhibition was determined as in Fig. 1 legend. 100% binding of MCF-247 was that level bound to KKT-2 cells treated in parallel without antibody. 1:1 nonfluoresceinated MCF-247 inhibition of binding showed a 43% inhibition of fluoresceinated MCF-247 binding. 100% antibody binding was that level bound to cells at the lowest dilution (1:12). Antibody binding (O————O); MCF-247 binding (△—————△); (³H-thymidine uptake experimental/³H-thymidine uptake control) × 100% (●————●). The curves represent data from three experiments ± standard deviation.

inhibitory antibodies should also inhibit antigen-induced proliferation of normal T-cell subsets. In fact, we present elsewhere evidence that the anti-Thy-1 monoclonal antibodies may inhibit concanavalin A mitogen and alloantigen induced T-cell proliferation (N. Hollander *et al.*, in preparation).

These experiments provide strong evidence that cell-surface MuLV-specific receptors on T lymphomas are involved in continued proliferation by these cells, as predicted by the receptor-mediated leukaemogenesis hypothesis[1-3]. The hypothesis, however, is not proven: for example, growth-inhibiting antibodies may affect cell proliferation by binding to molecules which generate antimitotic signals independent of viral receptors. Thus, prebound virus might inhibit antibody binding to a subset of antimitotic molecules, providing that the antimitotic subset is located near viral receptors. It is also known that some antigen-activated T cells may respond to T cell growth

factors by continued proliferation (in the presence or absence of antigen[16]). It is not yet known if KKT-2 cells belong to that category of cells, but the relative resistance of cells grown at higher density to growth inhibition by these antibodies might be due to these factors, or to higher concentrations of viral envelope determinants. Another potential difficulty with the hypothesis is the incidence of aneuploidy (trisomy 15) in AKR and RadLV-induced leukaemias[10]. While it is conceivable that this is not related to the leukaemogenic process, it seems more likely, that it is a necessary event in the progression to leukaemia[11]. Whether this is a necessary event related to cell-surface stimulation or some other aspect of unlimited cellular proliferation is still unclear.

It is interesting to speculate that other neoplastic cell types might also be regulated by stimulation of cell-surface mitogen-linked receptors by self-produced (or exogenous) complementary ligands. These cells also might be susceptible to growth inhibition by appropriate monoclonal antibodies.

Lateral diffusion of lipopolysaccharide in the outer membrane of *Salmonella typhimurium*

Melvin Schindler*†, M. J. Osborn† & Dennis E. Koppel‡

† Department of Microbiology, UCONN Health Center, University of Connecticut, Farmington, Connecticut 06032

Gram-negative enteric bacteria are enveloped by two membrane systems[1]. The inner or cytoplasmic membrane is responsible for the major metabolic functions including biosynthetic activities[2], while the major known functions of the outer membrane are primarily physical: it contains receptors for bacteriophages and bacteriocins[3]; it contributes to the maintenance of cell shape[4]; and it controls access of nutrient solutes and agents such as antibiotics and detergents to the cytoplasmic membrane[5]. Several investigations have indicated that mobility of membrane components, particularly lipopolysaccharide[5,6], is essential for biogenesis of the outer membrane[7,8], and is a primary

* To whom reprint requests should be adressed.

event in phage infection[9,10]. To define more accurately the fluid dynamic properties of the outer membrane as related to function, we have now developed the capability to measure lateral diffusion coefficients *in vivo* of rhodaminated G30 lipopolysaccharide fused into *Salmonella typhimurium* G30A filamentous bacteria. The method used extends the FRAP procedure (fluorescence redistribution after photobleaching)[11,12] to bacteria and the results demonstrate rapid diffusion of lipopolysaccharide $(D = 2.0 \pm 0.9 \times 10^{-10} \text{ cm}^2 \text{ s}^{-1})$ over micrometre distances.

In the FRAP technique, lateral transport parameters are determined from the characteristic redistribution of fluorescent label after a gradient of concentration is established by a localised photobleaching pulse. Gram-negative bacteria are in general too small to be studied successfully by this approach, but mobility measurements can be performed on bacterial filaments. Nonseptate filaments 50–100 μm long, consisting of a syncytium of bacteria sharing a common, continuous inner and outer membrane, were obtained by treatment with cephalexin[13] (see Fig. 1).

Exogenous fluorescently labelled lipopolysaccharide was incorporated into the bacterial outer membrane by vesicle fusion, following methods devised by Jones and Osborn[14,15]. The lipopolysaccharide was isolated from *S. typhimurium* G30 by the method of Galanos[16], further purified by electrodialysis[17], and reacted with rhodamine isothiocyanate following the procedure of Schindler *et al.*[11]. Unilamellar phospholipid vesicles containing the lipopolysaccharide were prepared, and incubated with a preparation of bacterial filaments for 40 min, at 37 °C. Jones and Osborn[14,15] have demonstrated that this procedure transfers lipopolysaccharide to the outer membrane of the acceptor bacteria. While vesicle derived phospholipid translocates to the inner membrane, the lipopolysaccharide does not, and resides exclusively in the outer membrane[14,15].

Electron microscopy was used to examine the surface distribution of vesicle derived lipopolysaccharide (see Fig. 2). For this purpose, lipopolysaccharide was derivatised with 2,4,6-trinitrobenzene sulphonic acid (TNBS) in order to incorporate trinitrophenol hapten (TNP) groups into the molecule. Vesicles

Fig. 2 Electron microscopy of *S. typhimurium* with and without exogenously added TNP-lipopolysaccharide. Freshly prepared TNP-lipopolysaccharide-phospholipid vesicles (phospholipid/lipopolysaccharide ratio = 60:1) were prepared and incubated with cells as described elsewhere[13,14]. TNP-lipopolysaccharide G30 was prepared as follows: 5 mg G30 lipopolysaccharide was reacted with 5 mg trinitrobenzene sulphonic acid (TNBS) in 1 ml 0.2 M NaHCO₃, pH 8.5 at room temperature for 1 h; the reaction mixture was applied to a Sephadex G-25 column (1.5 × 20 cm) and eluted with water; the void volume peak was lyophilised and stored at 4 °C. Goat anti-DNP antibodies (20 μl, 1.5 mg ml⁻¹) were added to the bacteria suspended in 1 ml, 50 mM HEPES pH 7.5 and allowed to incubate at room temperature for 5 min. The cells were washed three times with 2 ml buffer and resuspended in 1 ml of the same buffer. Ferritin-labelled rabbit anti-goat IgG antibody (0.2 ml, Cappel Labs) was added to the cells for 5 min at room temperature. The cells were then washed again three times in buffer, pelleted and fixed in 2% glutaraldehyde at 4 °C for 1.5 h. Thin section preparation was performed as described previously[14]. *a* and *b* are longitudinal sections while *c* and *d* are transverse sections of *S. typhimurium* with (*a, c*) and without (*b, d*) TNP-lipopolysaccharide. Scale bars, 220 nm.

Fig. 1 Bacterial filament viewed under dark-field light microscopy. *S. typhimurium* G30A was grown in PPBE from an overnight culture at a dilution of 1/20. After one generation of normal growth cephalexin was added to the medium (10 μg ml⁻¹). The culture was shaken vigorously and allowed to grow to $A_{600} = 1.0$. The culture was then diluted 1/10 in PPBE containing cephalexin (10 μg ml⁻¹) and again allowed to grow to $A_{600} = 1.0$. The cells were collected and washed with a 10 mM HEPES/cephalexin buffer pH 7.5. Superimposed on the filament, by photographic double exposure, is a 'picture' of the incident focused laser beam produced by imaging the fluorescence excited in a thin layer of concentrated dye solution.

were prepared and fused with non-filamentous *S. typhimurium* in the usual manner. After fusion, goat anti-DNP antibodies were reacted with the bacteria followed by incubation with ferritin-labelled rabbit anti-goat IgG antibodies. The samples were fixed in glutaraldehyde and thin sectioned for examination. Figure 2 demonstrates that the vesicle derived exogenous lipopolysaccharide is incorporated in the bacterial outer membrane.

Diffusion coefficients were determined by the FRAP technique using a recently introduced 'multi-point' analysis[12]. The labelled lipopolysaccharide was photobleached with a laser beam focused to a narrow band (~1 μm wide) aligned to intercept one or more bacterial filaments (see Fig. 1). The redistribution of mobile molecules along the filaments was then followed by monitoring the fluorescence intensity excited by an attenuated beam (×5 × 10⁻⁵) sequentially positioned at each of several locations in and adjacent to the bleached area.

Recovery curves of rhodamine-labelled G30 lipopolysaccharide in the acceptor bacteria G30A are shown in Fig. 3. From the functional form of the fluorescence recovery, it is clear that all the exogenously added lipopolysaccharide is free to diffuse in the outer membrane with no immobile components (recovery is greater than 90%). From a nonlinear least squares fit of the data to the appropriate theoretical equations[12], a value of $2.0 \pm 0.9 \times 10^{-10}$ cm^2 s^{-1} was found for exogeneously added lipopolysaccharide. Following addition of anti-G30 antibody, recovery is still monophasic, but now is very much slower with a calculated diffusion constant of $2.0 \pm 0.4 \times 10^{-11}$ cm^2 s^{-1}. This clearly indicates that the majority of lipopolysaccharide is situated in the outer membrane accessible to antibody molecules.

Mühlradt et al.[6], using indirect techniques, suggested that lipopolysaccharide diffusion is much slower ($D \leqslant 3 \times 10^{-13}$ cm^2 s^{-1}). A direct comparison of our results is not possible because those experiments were performed with wild-type bacteria in which the carbohydrate side chain on the lipopolysaccharide is much longer[1]. In addition, wild-type bacteria have approximately 2.5 times more protein in the outer membrane[18]. The effect of these parameters on lipopolysaccharide mobility is now being investigated.

The relatively rapid rate of diffusion that we observe for lipopolysaccharide is in marked contrast to the immobility of matrix-porin as determined by Smit and Nikaido[19]. Very similar diffusion characteristics for lipopolysaccharide and matrix-porin were observed by us in vitro, in reconstituted outer membrane multibilayers[11].

This work further extends to the FRAP technique which has previously been used exclusively on eukaryotic cells. The use of this technique should provide new and fundamental information

on the molecular dynamics of the outer membrane and the relationship of these dynamics to biogenesis and function of the membrane. The bacterial system is readily manipulable by genetic and physiological means, and can be used as a model for exploration of causal relationships between the molecular composition and organisation of a membrane, its fluid dynamics and specific functions (including receptor function and signal transmission).

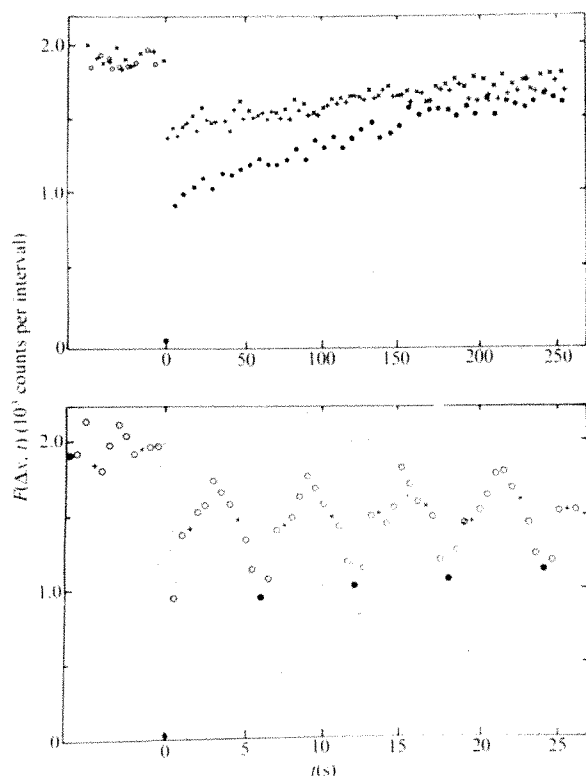

Fig. 3 Recovery curves of rhodaminated G30 lipopolysaccharide. Sample was bleached with an intense laser pulse focused to a narrow band intersecting the filament. Fluorescence intensity, $F(\Delta x, t)$, was measured as a function of position and time with an attenuated beam sequentially positioned at each of 12 equally spaced locations (0.36 μm separation) along the filament. Top: Recoveries measured at 3 of the 12 locations: coincident with the bleaching pulse (○), and 1.08 μm on either side of centre (+, ×). Bottom: Sequential scans including all 12 locations on an expanded time scale. Data were fitted to the form of equation (9) of ref. 12, assuming a 100% recovery.

A nucleosome-free region in SV40 minichromosomes

Edward B. Jakobovits, Susan Bratosin & Yosef Aloni

Department of Genetics,
The Weizmann Institute of Science, Rehovot, Israel

Simian virus 40 (SV40) DNA is found in infected cells in the form of a minichromosome[1]. It possesses a beaded structure composed of cellular histones and supercoiled viral DNA in a molecular complex which is very similar to that of cellular chromatin[2–4]. The similarity between these structures, and the fact that the major viral functions take place in cell nuclei via cellular machinery, have made SV40 an attractive model system in which to study the organization and expression of the more complex eukaryotic chromatin. Early studies on SV40 chromatin, attempting to determine the precise distribution of the histone beads (nucleosomes) along the DNA, indicated that the nucleosomes were randomly distributed relative to the viral DNA sequences[5–8]. This picture has recently been altered by a study indicating that a region close to the viral origin of replication is particularly sensitive to nuclease digestion[9–13]. Using a variety of nucleases,[10–13], the nuclease-sensitive region has been shown to map on a stretch of the genome beginning at the viral origin of replication and continuing about 400 base pairs into the 'late' side of the DNA. The simplest interpretations of the presence of a nuclease-sensitive region are that this region is either deficient in nucleosomal protein or that it contains a peculiar arrangement of these protein structures. We have analysed SV40 minichromosomes in the electron microscope in an attempt to determine whether alterations in the gross nucleoprotein structure of this region could be visualized. We report here that such an alteration does exist and that about 25% of SV40 minichromosomes observed contained a region of DNA between 0.67 and 0.75 map units which is not organized into the typical nucleosome beaded structure.
Fig. 1 Electron microscopic visualization of SV40 minichromosomes. At 48 h post-infection, SV40-infected BSC-1 cells were washed twice with 0.05 M Tris-HCl, *p*H 7.9, 0.001 M MgCl$_2$ and 0.005 M 2-mercaptoethanol (buffer H), and collected by low speed centrifugation. The cell pellet was resuspended in buffer H and centrifuged again at low speed. This procedure caused lysis of about 95% of the cells. The nuclear pellet was resuspended in 1 ml buffer H per 10^7 nuclei and incubated at 37 °C for 30 min with occasional shaking. The suspension was then centrifuged at 10,000 *g* for 1 min and the supernatant containing the SV40 chromatin was run through a 5–30% (w/w) sucrose gradient in buffer H containing 0.1 M NaCl for 2 h at 32,000 r.p.m. in the Spinco SW41 rotor at 4 °C. The 75S peak[30] (minichromosomes) was pooled, and immediately mounted on carbon membrane-coated grids activated by glow-discharge[31]. The grids were stained with 2% uranyl acetate and rotary shadowed with Pt/Pd (80:20). Molecules were visualized with a Philips 300 electron microscope, and photographs were taken at a magnification of ×42,000. *a*, Minichromosome without a gap; *b*, minichromosome with a gap, indicated by the arrow.

Figure 1 shows the appearance of representative SV40 minichromosomes with and without an exposed region ('gap') of DNA. Reproducibly we found that approximately 25% of the readable molecules contained a single gap, whereas molecules containing more than one gap comprised less than 1% of the population. We have measured the length of the 'exposed' region relative to naked SV40 DNA spread in the same sample. Figure 2 shows that the average length was 103±30 μm. Assuming the DNA to be fully extended, this gap corresponded to 320±90 base pairs of DNA. However, this length is a minimum estimate, as the spreading method used could not detect on the exposed DNA proteins that were able to cause the DNA's condensation.

To locate the gap relative to restriction sites on the physical map of SV40 DNA, minichromosomes were digested with site-specific, single-cut, restriction endonucleases. The extent of minichromosome linearization was dependent on the particular enzyme used. Digestion with either *Bam*HI or *Eco*RI converted only 20–30% of the minichromosomes to linear molecules, even in conditions of enzyme excess. Digestion with *Bgl*I produced 60–70% linear molecules. Similar proportions of linear molecules were observed when DNA extracted from minichromosomes digested by these restriction endonucleases was analysed by electrophoresis on agarose gels.
Fig. 2 Histogram of the length of the gap in the minichromosome. The length of the gap was measured in molecules as shown in Fig. 1*b*. SV40 DNA was used as internal length standard (1.7 μm).

Figure 3 shows the appearance of representative linear molecules that contain gaps, and Fig. 4 is a histogram showing the distribution of nucleosomes about the gap. When minichromosomes were cleaved with *Bam*HI, the exposed DNA stretch was located between short and long beaded arms, containing an average of 9±1 beads and 11±1 beads, respectively (Figs 3*a*, 4*a*). Similarly, when minichromosomes were treated with *Eco*RI, the gap resided between a short arm with an average of 6±1 beads and a long arm with an average of 14±1 beads (Figs 3*b*, 4*b*). Cleavage with *Bgl*I yielded a stretch of exposed DNA on the end of a string of nucleosomes averaging 19±1 beads (Figs 3*c*, 4*c*). Occasionally, we observed a solitary bead on the far end of the open stretch after treatment with *Bgl*I (see arrow, Fig. 3*c*). These results unequivocally locate the exposed stretch of DNA as starting at or very close to the *Bgl*I restriction site and extending into the late region for at least 320 base pairs. The high rate of cleavage by *Bgl*I indicated that in most molecules, the *Bgl*I cleavage site was not blocked by a nucleosome.
Fig. 3 Electron microscope visualization of SV40 minichromosomes cleaved with restriction endonucleases. The minichromosomes present in the 75S peak[30] of the sucrose gradient. (see Fig. 1 legend) were diluted into 1 volume of a solution containing 0.02 M MgCl$_2$ and 0.002 M dithiothreitol, and digested for 60 min at 37 °C with *Bam*HI, (*a*), *Eco*RI (*b*) and *Bgl*I (*c*), before mounting for electron microscope visualization as in Fig. 1. The cleavage sites are: *Bam*HI, 0.15 μm; *Eco*RI, 0.0 μm and *Bgl*I, 0.67 μm (see ref. 17). *Bgl*I cuts at the origin of replication[16].

Molecules without a gap possessed an average of 21±2 beads, regardless of whether or not they were linearized by restriction enzymes. Minichromosomes with a gap possessed an average of 20±2 beads, again independent of their linear or circular structure. Thus, cutting the minichromosomes with restriction endonucleases did not cause the loss of nucleosome structure due to slipping at the ends. The number of nucleosomes observed on the SV40 minichromosomes seemed to be similar in molecules with and without a gap. However, as the distribution of the number of nucleosomes is broad, we cannot distinguish between the possibility that the gap was generated during preparation by loss of one or two nucleosomes and the possibility that this site was devoid of nucleosomes *in vivo*. In the first case, the nucleosome(s) lost might be different structurally from those that remained associated with the DNA of the minichromosomes. One possibility is that they contain modified histones, which could cause the histone octamer (nucleosome) to dissociate easily from the DNA. It is also possible that in this region of the SV40 genome there is a transient binding of nucleosomes, or parts of nucleosomes, to only one strand of the DNA, as was recently proposed for eukaryotic chromatin by Palter *et al.*[14]. They suggested that this mechanism requires a major conformational change in the nucleosome, and we believe that such a change, if it occurs, may render the nucleosome unrecognizable in the electron microscope[15]. The exact mode of histone
Fig. 4   Histograms of the number of nucleosomes on each side of the gap in the cleaved minichromosomes. The analysis was carried out on molecules as in Fig. 3. The inserts diagram the linearized molecules showing the nucleosomes about the exposed region relative to the enzyme cutting site.

binding to single-stranded DNA may facilitate some, or all, of the regulatory signals that have been mapped to the exposed region of the viral DNA. These include the origin of DNA replication[16], the promoters for late transcription[17], the heterogeneous 5' ends of the late mRNA[18,19], the cap structures at the 5' ends of the late mRNAs[20-22] and a major binding site for viral T antigen[23,24]. That *Escherichia coli* RNA polymerase preferentially initiates transcription *in vitro* in this region of the SV40 minichromosome and asymmetrically transcribes the late strand (E.B.J., Y.A., S. Saragosti and M. Yaniv, unpublished results) also may support this possibility. In addition, the observation that transcriptionally active regions in eukaryotic chromatin are preferentially susceptible to both DNase I[25-27] and staphylococcal nuclease digestion [28] also indicates that similar 'gapped' structures may exist in cellular chromatin[15]. It should be emphasized, however, that we have not demonstrated that SV40 minichromosomes with an exposed region are the transcriptionally active viral chromatin. Although others have concluded that only a small fraction (0.5-3%) of the SV40 minichromosomes is transcriptionally active[29], we have observed that a much larger fraction of the minichromosomes is transcribed (unpublished). We are now investigating the correlation between gapped minichromosomes and transcription.

We thank M. Yaniv and S. Saragosti for communicating unpublished results and Dr D. Roufa for critical reading of the manuscript. This research was supported by USPHS research grant CA 14995.

Decreased rate of DNA-chain growth in human basal cell carcinoma

M. Heenen & P. Galand*

Biology Unit, Institute of Interdisciplinary Research and Department of Dermatology, School of Medicine, Free University of Brussels, 2 rue Evers, 1000 Brussels, Belgium

The DNA synthetic (S) phase of cell division is about twice as long in human basal cell carcinoma (BCC) as in the normal epidermis and several non-malignant skin diseases[1-3]. A similar increase in S phase duration seems to occur in tumours of the human oesophagus[4], larynx[4] and recto-colon[5,6]. At the molecular level, the overall rate of replication in a nucleus is determined by two factors—the frequency of initiation of replication and the rate of replication fork progression along the units of replication (for review see refs 7,8). Here we present evidence (based on DNA fibre autoradiography[9-11]) that the observed increase in S phase duration may be due to a marked reduction in the rate of DNA replication along replication units, the density of simultaneously operating replication units remaining unchanged. This indicates an alteration in some biological component(s) of DNA synthesis in BCC that is of potential interest for characterizing the malignant transformation of the epidermal cell and that may perhaps be exploited therapeutically.

We used biopsy samples from five normal subjects and three patients with basal cell carcinoma, small undifferentiated tumours with a multinodular structure (nodules 50–200 cells in diameter). The tissue samples were divided into lamellae about 1 mm thick, and labelled *in vitro* with a single specific activity of ³H-thymidine. We used a previously described DNA fibre autoradiography[9-11] with pulse periods of 30 and 60 min (see Fig. 1 legend). This provides valid estimates of relative rates of DNA synthesis only, based on the length of grain tracks in the fibre autoradiograph[7,12,13]. Similarly, in these conditions, centre-to-centre distances between adjacent tracks reflect the relative density of replicating units, rather than the absolute value[7,14].

Figure 1 summarizes the results by showing the distribution histograms of grain track lengths and centre-to-centre distances for pooled data from each tissue type. Cumulated frequency curves drawn for the two parameters allow estimation of their median value. The median track length thus obtained after the 30-min and the 60-min labelling period, respectively, were

Grain track lengths   Centre-centre distances
Fig. 1 Length and distance between centres of ³H-thymidine-labelled segments in DNA molecules isolated from normal cells and from basal cell carcinoma (BCC) of the human epidermis. Biopsy samples taken from the number of patients indicated in parentheses (informed consent was received from the patients) were divided into lamellae about 1 mm thick and prein-cubated in Eagle's basal minimal essential-diploid medium with 2×10^{-6}M 5-fluorodeoxyuridine (FUdR) to exhaust the endogenous thymidine nucleotide pool[25]. The tissue fragments were then incubated with 5×10^{-6} M ³H-thymidine (specific activity 40 Ci mmol⁻¹), FUdR remaining in the medium. After further incubation for 30 or 60 min, the tissue samples were rinsed and incubated at 37 °C for 30 min with 1% trypsin-0.3% dithio-erythritol (Sigma) dissolved in phosphate buffer, pH 7.8 to separate the epidermis from the dermis[26]. The process was furthered by a 10-s ultrasonic vibration at about 100 W using a Braunsonic 300 S apparatus (VWR Scientific). The dermis was removed by filtration through gauze, and the epithelial cells were further dissociated by another 10-s ultrasonic vibration (as above) (detachment of the dermis was assessed by microscopic examina-tion of histological preparations prepared at this stage). DNA fibre smears were then prepared as described by Lark et al.[27]. The smears (six slides per biopsy sample) were processed for autoradiography by dipping in K5-emulsion (Ilford) diluted at 50%. Exposure time was 45 days. Autoradio-graphs were developed for 2 min in Dektol (Kodak) and fixed. Grain track lengths and centre-to-centre distances were measured using a micrometric eyepiece and disregarding both end segments of tandem arrays on which measurements were effected. The results in each group were pooled ($n =$ total number of measurements obtained) and the mean is indicated. With both pulse durations the difference in the mean track length between BCC and normal epidermis was highly significant ($P < 0.001$, Wilcoxon's rank test), whereas there was no significant difference between distributions of centre-to-centre distances in any group and at any pulse duration. a, c, Normal epidermis; b, d, BCC.

10μm (range 8–12) and 17μm (range 15.3–17.3) for the normal epidermis and 6.3μm (range 5.2–6.7) and 12μm (range 9.7–12) for BCC. The higher track length measured in normal tissue does not seem attributable to a higher incidence of fusion between neighbouring units because the centre-to-centre dis-tance (1) was similar in both groups and (2) did not change significantly with labelling time. Also, few tracks were longer than twice the mean length, contrary to what would be expected if a high number of fused tracks were being registered[12]. Our data thus indicate that replication rate along DNA replication units is lower by a factor 1.5–1.6 in BCC than in the basal cells of the normal human epidermis.

To determine whether this might account for most of the relative lengthening (by a factor of about 1.8–1.9) of S phase duration in the cancer cells[1,2], it is necessary to consider what is known about the control of DNA replication during the S phase.

DNA replication in eukaryotic cells proceeds in a temporally and spatially regulated pattern, which seems species specific and preserved from generation to generation[7,8,11,15–18]. Coordina-tion of this programmed DNA synthesis implies that initiation is controlled by several sets of replication units sharing the same initiator (a protein, for example[18]) and/or a homologous recognition site[17,18]. It has been argued that the sequence of events that determines the duration of the S phase may cor-respond to the successive triggering of replication in sets (or 'banks') of replication units, by some event coupled to the synthesis of the preceding set in the sequence rather than by some external clock independent of DNA synthesis[19]. Accord-ing to such a model, a reduction in the rate of synthesis along replication units would result in a delayed initiation in the successive sets of units. This would result in an overall increase in S phase duration corresponding to the sum of as many delays as there are interdependent replication sets in the sequence.

For example, for an average centre-to-centre distance between tracks of 20 μm (our data), each replication fork must travel 10 μm to ensure fusion of adjacent units. A reduction by a factor of 1.5 in the rate of DNA synthesis in BCC would in that case extend the average replication time of synchronously replicating units by about 25 min (assuming a rate of fork progression of 0.2 μm min⁻¹ in the normal cell). If this were so, the observed 10-h increase in S phase duration in the tumour cells would imply that there is a sequence of 24 of the above considered sets of replication units (more, if the absolute rate of DNA synthesis in normal cells is slower), of which the initiation and the replication rate determine the S phase timing. The existence of sub-phases in S has been explicitly considered by several authors[20–22], but is difficult to prove because of the absence of markers for demarcating replication time zones[20].

However, other mechanisms, such as a change in the timing of DNA replication in a limited number of chromosomes or a difference in the process of chain termination[7,8], may also parti-cipate in the increase in S phase duration.

It is also possible that the phenomenon we have observed here is more pronounced in a particular sub-class of DNA (or of nuclei) that escaped detection. Indeed, our method probably leads to preferential scoring of the predominant class of DNA molecules present in the nucleus, and the most frequent nuclear type present in a given cell population. Again, based on higher nuclear fixation of ³H-actinomycin D in BCC (indicating a state of lower chromatin repression that would be consistent with the view that this tumour is derived from immature pluripoten-tial cells of the epidermis[23]), we previously considered[24] that an increase in the euchromatin–heterochromatin ratio might explain the longer S phase duration in the tumours.

At this stage we may only speculate on the molecular basis of the observed difference in the rates of elongation of DNA chains between normal and malignant epidermal cells. However, its potential importance for our understanding of cancer and as a possible rationale for chemotherapeutic investigation should prompt further study of this phenomenon.

Repeated folding pattern in copper–zinc superoxide dismutase

A. D. McLachlan

MRC Laboratory of Molecular Biology, Hills Road, Cambridge CB2 2QH, UK

Some globular proteins contain repeated structural patterns within the same polypeptide chain. Several enzymes[1–5] have a pseudo-symmetric two-lobed architecture: a pair of connected but well separated domains with very similar structures are grouped round an approximate 2-fold symmetry axis close to the active centre. On a smaller scale the same motif may appear inside a single protein domain: the polypeptide chain folds into two successive topologically similar subdomains which interlock symmetrically and form a compact globule[10–16]. In such a domain the two halves come into close contact round the dyad axis; as if the structural integrity of the domain depended on the interactions between its halves, while one separated subdomain could not exist as an independent folding unit. Many of these paired structures seem to have evolved from dimeric precursors by tandem gene duplication[17–19]. They contain repeated amino acid sequences or precisely repeated structural elements[3,6,13,20] in which equivalent sets of α-carbon atoms can be superimposed with root mean square deviations of the order of 1–2 Å. Here it is shown that copper–zinc superoxide dismutase[21–23] contains two paired subdomains, and the significance of the repeated folding pattern is discussed.

The copper–zinc superoxide dismutase from bovine erythrocytes has a structural core of eight antiparallel β-sheet strands which can be considered as either a flattened barrel[24,25] or a two-layered sandwich with four strands on each face (see Fig. 1A). The inter-strand connections are similar to those in the azurins[26,27] and the immunoglobin domain[28]; the β-sheet topology diagram[29] has a local dyad which relates strands d,e to g,h in the front face and c to f in the back face.

The topological dyad suggested that it might be possible to superpose the corresponding parts of the barrel. The shape comparison matrix method[10,30] was therefore used to compare every possible pair of α-carbon backbone segments which had a given fixed zone length. Segments were superposed by the rigid-body rotation and translation which minimized the sum of the mean square deviation distances.

Initial tests with zone lengths of 13,21 and 55 residues showed a local dyad on the back face relating strands b and c to e and f, with a further short repeat in the front face which related Gln 47 on strand d to Glu 119 on strand g. Further trials with α-carbon distance plots for the superposed parts revealed an extensive but interrupted structural repeat round the active centre (Fig. 1B). Here there are two long loops which extend between strands d and e on one side and between g and h on the other. When the central strands d and g which are related by the topological dyad

Table 1 Repeated structure in Cu-Zn superoxide dismutase

Atoms fitted	Results
Superoxide dismutase Cu—Zn face (d-loop-e to g-loop-h)	
37 = 109	28 atom pairs
39–51 = 111–123	R.m.s. deviation 1.58Å
53 = 125	Max. deviation 2.99Å
56–61 = 135–140	Rotation angle 177.9°
80–86 = 142–148	Shift along axis 0.32 Å
	Axis (0.984, −0.053, 0.173)
Superoxide dismutase back face (b-c to e-f)	
14–22 = 81–89	18 atom pairs
27–35 = 91–99	R.m.s. deviation 2.07 Å
	Max. deviation 3.31 Å
	Rotation angle 172.9°
	Shift along axis 0.71 Å
	Axis (0.810, −0.043, 0.584)
Both faces (c, d-loop-e) to (f, g-loop-h)	
27–35 = 91–99	37 atom pairs
37 = 109	R.m.s. deviation 3.17 Å
39–51 = 111–123	Max. deviation 5.07 Å
53 = 125	Rotation angle 177.3°
56–61 = 135–140	Shift along axis 0.28 Å
80–86 = 142–148	Axis (0.964,−0.019, 0.264)

The angles between the first two rotation axes and the third are 5.7° and 20.5°; between the first and the second, 25.8°. The Cu^{2+} ion lies within 2.1 Å of the screw axis through the Cu-Zn face. Note that although strand e is matched to strand h in the first fit and to strand b in the second, it cannot reasonably have an evolutionary relationship to both. The third fit suggests that e is related to h rather than to b. Another way of fitting both faces is to split strand e so that the first half matches half of b and the second matches half of h. The r.m.s. deviation is then considerably higher at 3.72 Å.

were superimposed large parts of the surrounding loops and strands e and h also fitted one another (Fig. 2 and Table 1) so that the front face has a high degree of spatial symmetry. In these superposition experiments no account had been taken of the active site metal ions, but the copper ion was now found to lie within 2.1 Å of the dyad axis and two of its histidine ligands, His 46 and His 118, lay in symmetrically equivalent positions. The zinc ion and its ligands lie to one side of the front face, enveloped by an irregular outlying loop (residues 62–79) which has no
Fig. 1 β-Sheet topology. A, Connections between eight strands a–h showing front active centre face d, e, g, h with copper ion in front centre and strands a, b, c, f of back face. B, Strands c–g and loops round active centre to show the symmetry. Black and white strands are related by local dyad centred about copper ion. The open circle off-centre represents a zinc ion.
Fig. 2 Active centre face of superoxide dismutase viewed along pseudo-dyad axis (central bar). Copper ion near dyad and zinc ion to upper right are joined to ligands by triple lines. Triple line to lower left is disulphide bridge Cys 55–Cys 142. Structure repeated across pseudo-dyad includes inner floor of β-sheet 37–46, corner 47, outer cross-strand 47–51, return cross-strand 56–61 and outer floor 80–86. Back face dyad relates 27–35 to 91–99 at upper rear. Copper ligands are His46, His 118, His 44, His 61. Zinc ligands are His 61, His 69, His 78, Asp 81.

partner across the dyad and rests against an extension of the opposite loop, residues 124–134. The local pseudo-dyad in the back face centred about strands *c* and *f* does not lie along the same line as the front dyad (see Fig. 2) and the two layers of β-sheet do not fit well to a single axis (see the third fit in Table 1).

A comparison of the amino acid sequences of the structurally equivalent regions[31] also shows that the tripeptide Val-His-Gln at positions 45–47 is almost repeated across the dyad as Val-His-Glu at positions 117–119. The histidines are copper ligands, both valines are buried in the core of the barrel, while the glutamine and glutamic acid residues lie at sharp corners where the β-sheet leads into a cross-strand. There are no other sequence repeats associated with the repeated structure, although a few isolated equivalent residues match: Asp 50, Thr 56, Gly 83 to Asp 122, Thr 135, Gly 145 in the front face; Val 27, Ile 33 to Val 92, Ile 97 in the back face.

These comparisons show that the active site face of superoxide dismutase is formed by two similar paired subdomains which interlock symmetrically and enclose the catalytically essential copper ion at the centre of a shallow pit between two matching curved loops of irregular β-structure. Two of the histidine ligands occupy structurally equivalent positions in a repeated tripeptide near the dyad and 28 α-carbon atoms from each subdomain match within a root mean square distance of 1.58 Å. Approximately 14 of the related atom pairs lie in hydrogen-bonded regions of the β-sheet strands, but 14 others belong to the irregular encircling loops.

Since there is no internal homology in the amino acid sequence and only a limited structural regularity in the back face of the enzyme, all these repeated features associated with the active site might be the result of convergent evolution. However, the structural similarity between the dyad-related α-carbon backbones of the half-domains is relatively precise and compares favourably with the repeats in parvalbumin[13,20] or pepsin[14,15]. All the features may then be relics of a very early gene duplication and the enzyme could have evolved in the following way. (1) It began as a symmetrical dimer with an exact dyad axis, formed of two three-stranded β-sheet subdomains *c*, *d*, *e* and *f*, *g*, *h* which included the long *d*, *e* and *g*, *h* enveloping loops—compare the third fit in Table 1. (2) A copper ion was bound on the dyad to histidines 46 and 118, forming a primitive active site between the subunits. (3) A gene duplication united the halves of the dimer. (4) At some later time β-sheet strands *a*, *b* were added, completing the barrel and shifting the centre of the back face. (5) A zinc binding site developed at one side of the copper centre and the enveloping loops expanded between residues 61–80 and 123–135.

Although the structural evidence for this sequence of events is indirect every step has parallels in steps which have been proposed for the evolution of other symmetrical enzyme structures[1,3,5]. The scheme would be consistent with the observation that the copper ion is essential for catalytic activity, while the zinc is not[32] and can be replaced by other metals.

Richardson *et al.*[28] have pointed out a very interesting structural parallelism between the β-sheet barrels of superoxide dismutase and the immunoglobin domains, which can be superposed with considerable precision. The immunoglobins also have internal pseudo-dyad repeats (to be described elsewhere) which are considerably more regular than those in superoxide dismutase. Surprisingly the dyads do not match when the two proteins are superimposed. In superoxide dismutase the dyad passes between residues His 44 and Val 116 which lie on the outer surface of the Cu-Zn face. These correspond respectively to Tyr 42 and His 93 in the V_L domain[28] of McPC603. The dyad also passes between Gly 31 and Val 95 on the back face, which align with Met 21 and Leu 79 in V_L. But the best dyad for the immunoglobin is displaced by one residue, passing between Trp 41 and Cys 94 on one face and between Ser 22 and Thr 78 on the other. This observation shows that it would be inconsistent to assume simultaneously that the two proteins have an evolutionary relationship and that both dyads also arose by gene duplication. Instead it seems probable that both barrels are independent realisations of a very restricted number[33] of allowed β-sheet topologies.

I thank Dr Jane Richardson for helpful discussions.

BOOK REVIEWS

Worlds in collision

William M. Kaula

FOR about 20 years now, A.E. Ringwood has been the most vigorous propounder of theories in two areas: the state and evolution of the Earth's mantle, and the origin of the Earth and Moon. The book reviewed here is an exposition of his ideas on the second topic. Another, heftier book of Ringwood's, *Composition and Petrology of the Earth's Mantle* (McGraw-Hill: New York, 1975) deals with the first topic; the contents thereof are recapitulated in the first two chapters of *Origin of the Earth and Moon*.

Ringwood's scenario of Earth and Moon formation is the most complete extant, which makes it a convenient entity to quote, amend or attack. This ˉrelative completeness results not only from Ringwood's energy and breadth, but also from two other factors: firstly, the explanation of as many features as possible by processes in the interiors of the Earth or Moon, the regimes with which Ringwood is most familiar; and secondly, a strong philosophical drive to adopt the simplest of hypotheses wherever possible. Baldly, the essence of Ringwood's current scenario is:

(1) The Earth, like the other terrestrial planets, formed from solid matter which had condensed in the cooling solar nebula.

(2) This solid matter came to the Earth in the form of planetesimals, the composition of which evolved moderately so that their total bulk composition is 85% a component "A" of metals and silicates condensing at temperatures above ᴧ1200°C and 15% a component "B" — "A" plus volatiles — principally alkali oxides, water, organics and sulphur compounds.

(3) Most of the volatiles were lost at planetesimal impact by being blown off by hydrogen liberated upon the interaction of iron and water.

(4) The iron core of the Earth formed early by the sinking of metal accumulations too large to attain chemical equilibrium with their silicate surroundings. One consequence was that appreciable traces of oxidized siderophiles (Ni, Co etc.) remained in the mantle.

(5) When core formation was essentially completed, a large body hit the Earth, vaporizing a lot of mantle material.

(6) An appreciable fraction of this

Origin of the Earth and Moon. By A.E. Ringwood. Pp.295. (Springer: Berlin, Heidelberg and New York, 1979.) DM45, $24.80.

material was lifted into geocentric orbit, primarily by the energy of the impact, but possibly helped by interaction of ionized material with the early geomagnetic field.

(7) The refractory component of this cloud condensed, and accreted together to form the Moon.

Most of Ringwood's text is devoted to the geochemical (primary) and cosmochemical (secondary) considerations which lead him to this chain of hypotheses: such matters as the compositional differences of the Earth and chondritic meteorites; the lighter element admixed with iron to account for the core density; the reasons for chemical disequilibrium in the Earth; accounting for density differences among the terrestrial planets; the trace elements in lunar rocks compared to terrestrial rocks and meteorites; etc. He does not attempt to develop detailed physical models of the stages outlined above (anyone who does so conscientiously will have many years of work before he can write a book). Nonetheless, Ringwood's ideas are congenial to planetary physicists and dynamicists whose minds are unable to span the dizzying leap, from the nebula dust to the present bodies, required by those who hypothesize that compositional differences among planets arose from the same processes as compositional differences among meteorites.

The key evidence pertinent to lunar origin emphasized by Ringwood is the similarity of abundances of unvolatile siderophiles between the Moon and the Earth — with one exception (always exceptions in this game) within a factor of two among the elements examined. In contrast, there are appreciable depletions of more volatile siderophiles in the Moon compared to the Earth. These unvolatile siderophile abundances are much less than in chondritic meteorites, but much more than would occur in rocks crystallizing in equilibrium with metallic iron (which one category of differentiated meteorites, the eucrites, are believed to demonstrate). The great deficiency of iron in the Moon

required by its low mean density and absence of volatiles indicates prior planetary differentiation. Primordial isotope ratios, as well as dynamical feasibility, indicate that this differentiation was either in the Earth, or in other bodies at about the same distance from the Sun. The complete absence of any evidence of these other bodies in the meteorite population is the strongest argument in favour of the Earth for the locus of the differentiation.

The persuasive (although not overwhelming) lunar siderophile evidence comes from examination of low-titanium mare basalts, which are thought to be the consequence of rather high percentage partial melts deep within the Moon. More recently, Ringwood and collaborator John Delano have presented evidence of indigenous siderophiles in lunar highland rocks and soils, an exercise requiring subtraction of a considerable meteoritic contamination, explanation of enrichment of the more volatile elements by "impact mobilization", etc. Here, Ringwood's drive to marshal all possible evidence in favour of a simple synthesizing hypothesis has again put him on the minority side of a rather technical debate. He was also, for example, about the last prominent petrologist to abandon the hypothesis that mare basalts were drawn entirely from source materials identical in composition with the bulk of the Moon.

Nonetheless, Ringwood's synthesizing drive, plus his physical intuition and sense of the issues, make this book the best introduction available to the main scientific debate generated by the Apollo project data, as well as a good target for his colleagues to snipe at. The reader coming from another scientific field will probably find much of the reasoning casual or *ad hoc*, the variety of data presented bewildering and the tone more one of strident advocacy than calm objectivity. These properties are not peculiar to Ringwood, but are rather characteristic of the field: strong intuitive biases are necessary to get anything done, and not be paralysed by indecision. The time for a Euclid is still far off. Meanwhile, a good book with much food for thought. □

William M. Kaula is Professor of Geophysics at the University of California, Los Angeles.

Of mercury and man

Roy Harrison

The Biogeochemistry of Mercury in the Environment. Edited by J.O. Nriagu. Pp.696. (Elsevier/North-Holland: Amsterdam, Oxford and New York, 1979.) $136.50, Dfl.280.

THERE are few toxic substances with a history as long as that of mercury. The metal has been known and used for at least 3,500 years and still finds wide application today. There are documented instances of inorganic mercury poisoning dating back 500 years, and alkylmercury poisoning has been known for over 100 years. Yet mercury still provides surprises. Although the first cases of Minamata disease occurred in 1953, it was not until 1959 that alkylmercury poisoning was identified as the cause with any degree of certainty. Until that time, although occupational alkylmercury poisoning was known, the possibility of poisoning of the population by environmental exposure, in this case by

consumption of fish which had absorbed alkylmercury from the effluent of a local chemical works, had not been suspected. It was not known that fish could concentrate alkylmercury from water, nor was it discovered until later that alkylation of inorganic mercury in aquatic sediments was possible.

Minamata and other incidents of mercury poisoning have stimulated more interest in mercury as a pollutant than in any other toxic agent with the possible exception of lead. Biogeochemistry, a new term to me, apparently embraces "the chemical behaviour and biological effects of mercury in the biosphere, geosphere and hydrosphere". In Nriagu's own words, it provides "the logical conceptual framework for looking holistically at the mercury cycle and the human impact upon it". These are grand ideas and to a large measure the book lives up to them. The coverage is extremely broad, including the production, uses and control of mercury, the environmental chemistry and biological effects of the metal in terms of occupational and environmental human exposure, and the effects on aquatic and

terrestrial organisms. It includes detailed analyses of the outbreaks of organomercury poisoning at Minamata and Niigata in Japan (both due to consumption of contaminated fish) and in Iraq (due to the consumption of grain seed treated with mercurial fungicides).

The book contains 24 chapters, each written by specialists in a particular area. The result is quite impressive; there is a wealth of information which should satisfy most workers in this field, with relatively little overlap between contributions. Each chapter contains a large bibliography which is in most instances fairly up to date (references up to 1978 are included). As with much review material nowadays there is rarely any attempt at critical analysis, some chapters being little more than a listing of relevant work. That criticism aside, this book represents a valuable contribution for which many workers in this broad transdisciplinary field will be grateful. □

Keeping up in physics

W. Cochran

A Perspective of Physics. Volume 3. Introduction by Sir Harrie Massey. Pp. 360. (Gordon and Breach: New York and London, 1979.) $35.50.

IN 1695 delegates from the four Scottish Universities met as a Commission "to consider methods of instruction in philosophy". Their comments on draft reports covering various parts of the subject have been preserved, and we read for instance that "One part of the delegates are of opinion that Newton's hypothesis of the ebbing and flowing of the sea should be insert, or a reason given why it is not; and the other part think that there is no need to make any mention of it. The author gives this reason why he omitted it — because neither he nor any he has conversed with on the subject do so fully understand what Newton does write thereon as they can make it intelligible to young students". Any university teacher of physics who smiles at this in 1980 should do so wryly, for we have by no means solved by specialization that problem of keeping up to date with the advances made in our subject.

Volume 3 of *A Perspective of Physics* contains a selection of the articles which appeared in *Comments on Modern Physics* during 1978. This series appears in five sections, Nuclear and Particle Physics, Solid State Physics, Astrophysics, Atomic

and Molecular Physics, and Plasma Physics. In 1978 about 100 short review articles appeared under one or other of these headings, and of these 29 are reproduced in the volume under review. The emphasis is on brevity; a typical article is 3000–4000 words in length, with 20–30 references. Topics range from "Charge Density Maps in Chemisorption" to "New Quarks and Old Ones Too", and Sir Harrie Massey is remarkably successful in putting the articles into perspective in his introduction. I must admit, however, that

while I shall continue to read *Comments on Solid State Physics* as it appears, personally I find most other reviews in this series too terse and too specialist-directed when compared with those in, for example, *Physics Today.* We are better placed than our predecessors were three centuries ago, but there will never be an easy solution to the problem of understanding advances in physics. □

A vitamin D encyclopaedia

D.R. Fraser

Vitamin D. The Calcium Homeostatic Steroid Hormone. By A.W. Norman. Pp.496. (Academic: New York and London, 1979.) $48, £27.

KNOWLEDGE about vitamin D, we are told, falls into eras. There was the era of ignorance before 1920, then the era of vitamin D chemistry and nutrition, followed by the 15–20-year era of vitamin D metabolism. We are now it seems in the era of vitamin D reviews, with recent books entitled *Vitamin D* being produced by D.E.M. Lawson (Academic: New York and London, 1978), H.F. DeLuca (Springer: Heidelberg and New York, 1979) and this one by A.W. Norman, plus a myriad of review articles throughout the biological literature. Truly

the subject is well publicized.

One must admire the energy and enthusiasm resulting in this latest account. The work aims and succeeds at being comprehensive. There are detailed descriptions of the chemistry, metabolism and function of vitamin D, with chapters reviewing the historical development of the topic and the medical relevance of the new knowledge. All this is supported by an extensive bibliography, the dates in which indicate a minimum delay in the publication process. It is an admirable book of reference on all aspects of the biology of vitamin D.

On the other hand it is also the vitamin D gospel very much according to Norman, and hence tends to be a catalogue of the notable achievements of the author and his colleagues. But in a curious way an opportunity has been missed here to give a lead in unravelling the complexities of vitamin D function. Rarely does the author allow his own insight to throw new light on this problem. Yet the mysteries of the mechanism of action of vitamin D are now more amen-

able to attack by imaginative intellect than they ever were in the experiments of the past.

Obviously with just one author, the significance of each finding receives very personal assessment. One might wish that more emphasis had been placed on the discovery of the 25-hydroxylation reaction which was the key finding in the identification of functional vitamin D metabolism. There is also a pervasive, conscious attribution of discovery to discoverer to the point of obsession. After noting the seventeenth century descriptions of rickets by

Whistler and by Glisson, it was concluded "only fair and reasonable to give both authors credit for first priority". With the passage of time do scientists really care who did what first?

It is helpful to have the author's special knowledge of such topics as the relationship between structure and biological activity of vitamin D and the use of filipin in studies on calcium transport. It is possible to ignore the smattering of errors which mar the text but perhaps it would be wise to correct the bizarre footnote on

aflatoxin (p.446) in any subsequent edition. There are many attractive figures and tables to illustrate the work; in some of these their artistry exceeds their comprehensibility (e.g. Fig. 6-22).

Using some of the author's favourite words, this book could be described as an exceedingly potent, dramatic, and unequivocally massive, herculean effort. It's also quite a good read. □

D.R. Fraser is at the MRC Dunn Nutritional Laboratory, University of Cambridge, UK.

Nodules in depth

Roger G. Burns

Manganese Nodules. By R. Sorem and R. Fewkes. Pp.723. (IFI/Plenum: New York and London, 1979.) £59.85.

MANGANESE nodules are intriguing marine deposits because contained in the very fine-grained matrix are accumulations of the strategic metals cobalt, nickel, copper, manganese and molybdenum. Understanding how these deep-sea ferro-manganese oxide concretions formed, and the processes by which the transition metals became enriched in the constituent manganese and iron oxide phases, requires access to very high resolution observational and analytical instrumentation. Sorem and Fewkes have catalogued data compiled at Washington State University during the past decade for several hundred marine manganese nodules using techniques of ore microscopy, X-ray diffraction, X-ray macroprobe and electron microprobe analyses. Almost half of their book consists of photographs of polished sections of manganese nodules collected from the Pacific Ocean as well as some specimens from the Atlantic and Indian Oceans. The remainder of the book documents data and describes methods used to study each of the nodules.

Five introductory chapters in Part 1 of the book (142 pages) provide detailed accounts of procedures to prepare polished mounts of manganese nodules and to photograph them in reflected light. Techniques are described for obtaining microsamples for mineral identification by X-ray diffraction, and analysing the nodules non-destructively by X-ray macroprobe and electron microprobe methods. Results of studies of internal textures, mineralogy and probe analyses of some of the nodules are given and attempts made to interpret the data. The text reads like a self-centred report to a funding agency; reference to pertinent work of other investigators is minimal.

The second part of the book (581 pages) is an encyclopaedia of data sheets and photomacrographs of almost 300 nodules

studied. The reflected light photographs of the polished sections are superb; they provide a plethora of information on the diverse internal structures and growth histories of the nodules. The data sheets painstakingly summarize the seafloor locations, physical properties and available laboratory data for each of the nodules. The features soon become repetitive, however, contradicting the authors' declared major purpose of the volume, which is "to provide the interested investigator with a factual record of the internal features of *typical* nodules".

Most of the information contained in the book is now well known to scientists studying manganese nodule geochemistry. One might question whether the frequency of occurrence of birnessite reported by the authors alone is an artifact of conditions (air drying; vacuum impregnation) used to prepare and mount their manganese nodule specimens. Current investigations indicate that delta-MnO_2 (vernadite) is as abundant as todorokite, the major host of nickel and copper, in Pacific nodules. Some of the observations and interpretations made by the authors have been superseded by results from more modern high-resolution techniques, including scanning electron microscopy and energy dispersive analysis, transmission electron microscopy and selected area diffraction, infrared and extended X-ray absorption fine structure spectroscopy. The authors do not refer to the wealth of information on synthetic mineral analogues and bacteriological studies relating to the stability and formation of manganese oxide phases hosting transition metals in manganese nodules, which drastically modify internal structures and microchemistries of manganese nodules.

The prohibitive price means that it is unlikely that individuals will buy this book. However, the magnificent photographs make the volume a showpiece for coffee tables and library display shelves. □

Roger G. Burns is Professor of Mineralogy and Geochemistry at Massachusetts Institute of Technology, and is currently a principal investigator in the Manganese Nodule Project funded by the International Decade of Oceanography Program of the National Science Foundation.

Two on physical and theoretical chemistry

J.S. Rowlinson

Statistical Thermodynamics of Simple Liquids and their Mixtures. By T. Boublik, I. Nezbeda and K. Hlavaty. Pp.145. (Elsevier: Amsterdam and New York, 1980.) $41.50, Dfl.85. *Weak Intermolecular Interactions in Chemistry and Biology.* By P. Hobza and R. Zahradnik. Pp.346. (Elsevier: Amsterdam and New York, 1980.) $48.75, Dfl.100.

THESE two monographs are the second and third in a series called "Studies in Physical and Theoretical Chemistry". Both are by Czech authors, and both are out-of-date, but there the resemblance ends. The book by Boublik and his colleagues is a compact and balanced account of the statistical mechanics of model liquids composed of spherical particles. There is a short chapter on integral equations for the molecular distribution functions and two long chapters on perturbation theory. The treatment is good on the mathematical details but cursory on the comparison of theory with the results of computer simulation, while real liquids receive but the barest mention. There are only two references later than 1974 (both Czech) and so the book is silent on the most rapidly growing part of the field in the last ten years — the extension of theories to deal with non-spherical molecules. Within these limitations it can be recommended to those who want a clear account of the authors' chosen field, and are prepared to pay the stiff price.

Weak intermolecular interactions is, perhaps, a more challenging subject since so many techniques contribute to its study: spectroscopy of many different kinds, molecular beam scattering, thermodynamic and transport properties, quantum mechanics and both equilibrium and non-equilibrium statistical mechanics. It is challenge that this badly balanced

book quite fails to meet. It starts with a pedestrian but well-referenced chapter on quantal calculations, which omits the estimation of dispersion forces from transition moments, and overlooks the existence of multibody forces in condensed systems. It starts to go badly wrong when it gets to experimental methods and their interpretation. Inversion of macroscopic properties to give intermolecular potentials

is wrongly described as "rarely successful", electronic spectroscopy of dimers is dismissed in seven lines, and molecular beams in two pages. The section on the determination of intermolecular forces from viscosity is so misjudged that it quotes equations appropriate to the theory of the viscosity of liquids whilst only gases have been used for this purpose. The final chapter, "Applications", has some more

interesting pages but it is often uncritical and repetitious. Even the useful information in the book is difficult to find without an index of systems. This disappointing book can be recommended neither to chemists nor to biologists. □

Thirst work

M.J. McKinley
and J.F. Nelson

The Physiology of Thirst and Sodium Appetite. By J.T. Fitzsimons. Pp.572. (Cambridge University Press: Cambridge, UK, 1979.) £32.50.

RENEWED interest in the study of thirst mechanisms has resulted from the experimental contributions made over the past two decades by James Fitzsimons. The last major work on this subject, *Thirst* by A.V. Wolf (Charles C. Thomas: Springfield,

Illinois, 1958), appeared more than 20 years ago and, in view of the burgeoning experimental activity in this field since then, Fitzsimons' new book is a timely and comprehensive account of knowledge on thirst.

His book is the latest of the series of monographs published by the Physiological Society. Designed primarily for readers at the level of graduate student and above, it gives a lucid analysis of the causes of drinking, discusses the comparative physiology of drinking in vertebrates, dissects the effect of cellular and extracellular dehydration, and assesses the roles of hormones and the renin-angiotensin system on drinking behaviour. A survey of the pharmacology of drinking

and clinical aspects of thirst is included as well as a chapter on sodium appetite.

It is perhaps an unfortunate necessity that, as recognized by the author, the book is no more than an interim account. Thus few of the more than 700 references cited are to results published by others during the last three years. As a consequence, for example, the importance placed by him on the renin-angiotensin system as a stimulus to thirst would now be disputed by a number of other investigators in the field.

The chapter on sodium appetite has a number of deficiencies. This is primarily a consequence of defining sodium appetite as "an innate response to sodium deficiency, that causes animals to seek and ingest sodium salts", a restrictive definition. Thus evidence which demonstrates clearly that glucocorticoids stimulate sodium appetite has been overlooked. In fact the author claims that "glucocorticoids have little if any action on sodium appetite". It also appears to be inconsistent with such a definition that he recognizes that sodium appetite increases in both rats and rabbits during pregnancy and lactation where the changes are almost certainly due to alterations in hormone secretion and not to sodium deficiency.

The synthesis of the large salt appetite of pregnancy and lactation by appropriate sequential administration of physiological amounts of steroid and peptide hormones has been shown. The experiments closely parallel those on induction of maternal behaviour by similar hormone dosage. They hardly leave any conclusions on the role of these hormones as hazardous, as the author suggests, unless quite different criteria are applied to those advanced by him for a physiological role of angiotensin in thirst. Some minor inconsistencies and errors (e.g. p.100 lists plasma K of humans as 6.3mM) in the text were also noted.

Despite these limitations the book makes a very significant contribution to the dissemination of knowledge in this rapidly advancing area of physiology, and will no doubt become a standard reference work on thirst. □

Hagfishes and lampreys

Lis Olesen Larsen

Biology of the Cyclostomes. M.W. Hardisty. Pp.428. (Chapman and Hall: London, 1979.) £20.

THOSE who wish to elucidate the early stages of vertebrate phylogeny often examine only one, or at most two, cyclostome species. Further, such studies have too often been based on a few animals, badly described as to prehistory, stage of development, sex etc. This makes much of the ample literature on cyclostomes (hagfishes and lampreys) rather superficial. Professor Hardisty, however, has spent a lifetime in devoted study of many aspects of lamprey ecology, physiology and morphology. Recently retired, he has made in this book an impressive effort to summarize what is known about lampreys and hagfishes. His main intention is to discuss the early stages of vertebrate phylogeny by comparing all aspects of the two groups. His basic assumption is that although cyclostomes are no longer considered directly ancestral to the gnathostomes, they are more likely to have retained characters of "the unknown vertebrate ancestor" than other vertebrate groups.

Each chapter compares lampreys and hagfishes, and the topics range from palaeontology, ecology, physiology and

morphology, to biochemistry and molecular biology. In a final chapter Hardisty tries to draw conclusions about evolution on the basis of an integrated view of the life of hagfishes and lampreys. Thanks to his honest discussions, this chapter made it clear to me (but not to him) that his basic assumption is not necessarily true. The probability of finding primitive characters in present-day vertebrates may be equally large in any vertebrate group. In addition our hypotheses about evolutionary pathways are always marred by the difficulties in distinguishing between primitive and specialized characters, and in knowing when changes are adaptive (that is caused by natural selection) and when they occur by chance. The latter possibility is not seriously considered by Hardisty.

Throughout the book the author lists differences, between lampreys and hagfishes and between cyclostomes and gnathostomes, in attempts to establish how these three groups relate to one another. In order to obtain knowledge about the vertebrate ancestor(s!) it may be equally useful to look for similarities among these three groups, and between each of them and the various invertebrate and protochordate groups.

The book is recommended for all who want to study cyclostomes. They will find a useful, broad and detailed basis for their studies and an updated list of references. □

M.J. McKinley is a C.J. Martin Research Fellow and J.F. Nelson a Senior Research Officer of the National Health and Medical Research Council of Australia. Both are employed at the Howard Florey Institute of Experimental Physiology and Medicine, University of Melbourne, Victoria, Australia.

nature

29 May 1980

Watching other people's television

THAT nations, especially new nations, equate their independence with the existence of a national airline is well-known. A separate broadcasting service has more recently also come to seem a symbol of nationhood. It is not merely that heads of state, or their chief executives, consider themselves diminished and demeaned if they cannot from time to time address messages of some kind to their people. Nobody will deny the social and political value of a national television service, potentially at least, in helping to reinforce people's sense that they belong to the same country.

Unfortunately, however, the chauvinism that argues the benefits of national broadcasting services is all too often matched by a xenophobia that amounts to downright suspicion of other people's broadcasts. So much, for example, is apparent in North America, along the forty-ninth parallel — a circumstance that fortunately does not prevent privately-owned Canadian television networks from re-distributing signals picked up from across the border. Along the frontiers within Western Europe, indifference and polite curiosity are probably the hallmarks of people's regard for such neighbouring television transmissions as they can pick up. The frontier between East and West Germay is, on the other hand, much more powerfully charged with television xenophobia. Hitherto, however, sources of strife such as these have been relatively few and far between, largely because of the limited range of ground-based television transmissions. There is now a prospect that this will be changed with the arrival of the first direct-broadcasting satellites some time in the early 1980s.

Already, in Britain, Sir Harold Wilson, the ex-Prime Minister, has talked of the way that British cultural traditions may be undermined by television transmissions (accompanied by corresponding advertising material) from mainland Europe. Elsewhere, similar fears are matched by a sense of opportunity — or even by the hope of commercial profits from novel television channels carrying a mixture of news, entertainment and advertisements to very large numbers of people. Moreover, there is no reason to suppose that the plans which have been laid for the setting-up of direct-broadcasting services are in any way defective.

Geosynchronous satelites operating at centimetre wavelengths will be able to transmit signals powerful enough for television pictures with good definition to be received on individual parabolic dishes one metre or so across. Both in Canada and France, systems such as these are intended to provide cheaper and more effective means of broadcasting existing national services than can be had with the present cumbersome system of ground-based transmitters, land-lines and relay stations. So what are the international implications of these developments? And how valid is Sir Harold Wilson's concern?

First, it must be acknowledged that the system for regulating the use of direct-broadcasting satellites internationally is, bluntly, a muddle. By international consent, the regulatory body is the International Telecommunications Union, which was a great success in the first few decades of its history, when the problems were largely those of arranging that the same countries did not use the same frequencies for long-distance radio trasmissions, long or short-wave. Since then, unfortunately, demands on the electromagnetic spectrum have increased, while novel technical developments such as the direct-broadcasting satellite have failed to conform with the precedents for international compromise worked out in the early years.

Faced, two years ago, with conflicting requests for spaces for satellites along the geosynchronous orbit, the technical committees of the ITU for all practical purposes threw up their hands in despair and chose to allocate to each member state the equivalent of five channels of television broadcasting from geosynchronous orbit. Neither need nor the likelihood that the facilities thus made available would be used was part of the calculation. The result is that in some parts of the world (North America, for example) the would-be broadcasters are unduly contrained, while elsewhere opportunities are likely to be neglected for some time to come. Moreover, while the consents which have been made by the ITU are accompanied by technical definitions of the strength of the signals from broadcasting satellites, so that the footprints on the surface of the earth will be constrained, signals from orbit will inevitably spread further across national frontiers than signals from terrestrial transmitters.

So much is clear. Technically, the first broadcasting satellites could be in service as soon as 1983, both in Europe and North America. It is much less certain what uses will be made of the new technology, and whether the international consequences will be anything like as serious as some have suggested. The fear, for example, that broadcasting satellites might be used to flood various parts of the world with propaganda from another have been to a large extent undermined by the willingness of the member governments of the ITU to accept the technical restrictions put on the footprints from "their" satellites — and by the recognition that a whole population would have to find a way of concealing a metre-dish in every attic before propaganda satellites could be effective.

The more immediate international consequences of the new technology are likely to be in Western Europe, a region divided by its Common Market. Sir Harold Wilson's instincts are to that extent correct. At least in the short-term, however, his fears are misplaced. Britain is divided from the mainland not merely by the English Channel but by the technical specification of its television signals, and from both France and Germany by language. Much the same is true elsewhere in Europe — which is not universally a cause for self-congratulation. It follows that television signals from other people's satellites will be a serious cultural problem only if and when steps are taken to devise not merely their characteristics but their content so that they will compell and hold the attention of Europe's polyglot population.

This will be no light undertaking. One of the attractions of satellite broadcasting is its cheapness. A few tens of millions of dollars will put a satellite in orbit, while the cost of servicing it from the ground with signals is unlikely to be much greater over a period of five years, say. Television broadcasters are, however, these days painfully aware that the cost of burdening the signals their transmitters put out with a content that people want to look at is very much greater. Both in Switzerland and the Low Countries, there are still unformed plans for launching (in both senses of the word) such television services, using channels allotted by the ITU to governments that will, in all probability, be unused. Given that the success of ventures such as these will depend entirely on the skill with which the content of what is broadcast is devised, can anybody make a case that they should be crabbed? Would it not, rather, be more generous and far-sighted to agree that a successful international television service must be inherently desirable and that it should therefore be encouraged? The only basis for holding to a different view must be a conviction (for which there is no evidence) that all television is bad, so that more must be worse.

If the immediate consequences of television satellites are likely to be less serious than people have been suggesting, it does not unfortunately follow that nothing should be done. Nationally, governments will have to look to the arrangements they use at

present for controlling the content of national television broadcasting. Over the years, all liberal governments have laid down rules for guiding the operations of those with a licence to broadcast electromagnetic signals — and from time to time they have prosecuted those who have chosen to violate their airspace as if they were literally pirates. If international broadcasting proves financially feasible, governments will have to reconcile themselves to having less direct control. (They may even be faced with the prospect that national politicians denied the exposure they would like on their national network would go off and hire time elsewhere, a development that might serve to put political broadcasting in perspective.) But this is a prospect that must in any case be faced. Other technical developments, cable television

for example, are similarly a threat to the traditional paternalism of governments and their regulatory bodies.

It will also be necessary to look again at the mechanism by which the ITU sets out to allocate positions along the geosynchronous orbit. For more than the coming decade, and until still higher electromagnetic frequencies are useable, the geosynchronous orbit will be a scarce resource. It is absurd that it should be shared out like a pack of cards. Means of counting need in the calculations should urgently be sought. And some thought should be given to the use of satellites as a means of making television signals internationally accessible by individuals with the wish to enjoy this luxury (and the willingness to pay for it). Television as such is valuable.

Let Finniston cool his heels awhile

THE British Government is taking its time in responding to the report of the Finniston Committee on engineering education published last year (*Nature* **279**, 352; 1979), and with good reason. The Department of Industry is planning to make public some kind of an opinion late this summer, but the Department of Education and Science will still then be taking outside opinion. It is exceedingly unlikely that the government will have hit on a policy before this year is out. Others than the impatient members of the Finniston Committee, some of whom appear to have mistaken their report for the Mosaic Tablets, will welcome a breathing space before an important part of British higher education is thrown in the melting-pot.

British governments, like their taxpayers, have been worrying about engineering education ever since the end of the Second World War. At first, the chief concern was that universities were not producing enough graduate engineers to take their places alongside those trained in more traditional ways, essentially by apprenticeship. That defect has now been remedied and the annual output of graduate engineers (from polytechnics as well as universities) approaches 20,000. Concurrently, its traditional route has been closed. More recently, interest has centred on the character and even the quality of engineering education, provoked chiefly by the reflexion that the faults of British manufacturing industry must somehow be attributable to the engineering professors up and down the country.

Few would argue that British engineering education is blameless. It is, for example, difficult to understand how British universities are confident that three years of higher education will enable a man or woman to function as an engineer (albeit under the supervision for a time of one of the engineering institution) when most other educational systems consider three years insufficient. There is also ample if anecdotal evidence to suggest that British engineering education is too much dependent on lectures, too theoretical and too much detatched from the practical problems of practising engineers. Not even the Finniston Committee has thrown light on questions such as these, however. Although it is possible to understand why it concentrated instead on the problems of how best to enhance the public prestige and the self-esteem of the engineering profession, a valuable opportunity has thus been missed. And the engineering departments, conscious as many of them are of the need for qualitative change, have no solid foundation on which to base reform.

While the Finniston Committee was sitting the initiative was stolen by the University Grants Committee, which announced two years ago a scheme under which selected universities (seven in total) would be given extra resources in order to provide four-year engineering courses for more able students differing from those of conventional pattern in that their curriculum would be "enriched" with elements of management science, industrial

relations and the law. The UGC courses were also devised so that students would spend some of their time gaining first-hand experience of what was considered two years ago to be the sector of British industry most in need of improvement — manufacturing industry. A few years from now, when the first graduates of these courses are in jobs, it may be possible to tell whether the experiment has been successful, although the chances that an objective assessment will be possible are diminished by the lack of formal criteria by which that might be done.

On the engineering curriculum, the Finniston Committee accepted that the UGC's experiment should be the model for training the most able engineering students. To that extent, the experiment is an experiment no longer. The committee's chief educational concern was to ensure that there would be funds enough to support such courses (and the student following them) wherever in Britain engineering is taught. To this end, the committee asked that its proposed Engineering Board, whose function it would be to supervise professional standards, should also have at its disposal funds with which to supplement existing ways of chanelling public money to universities and students.

This proposal is beguiling but is also a trap. Naturally it has the appearance of virtue at a time when the belief persists that a *something,* almost anything, must be done. Understandably, engineering departments are also sympathetic to the notion that more funds should come their way. But changes of the kind proposed, while helping to change the education of engineers in a direction not yet proven, would certainly change the character of British universities in a way that cannot be welcome. In their essentials, these Finniston proposals are tantamount to asking that engineering departments in British universities should be dealt with differently — and more generously, than other departments, and that engineering students should often receive higher stipends. Little imagination is needed to guess how divisive these provisions would be. And there is no evidence that their promised benefits would materialise. It is no wonder that the government's response is hesitant.

Already there are signs that British universities are more jealous of their autonomy than they are skilled at exercising it. Will their interests in the long run be served if an important part of their contribution to the national interest is controlled and financed from outside? (Although there are similarities with medical education, Finniston's proposals for engineering education go much further than the General Medical Council would dare dream.) May it not be that the universities' best course of action, in this as in other matters, would be to carry out their own more constructive examination of the problem? Nobody would be surprised if it then turned out that what is wrong with British engineers is that industry makes too little use of them.

Risk assessment by numbers

Washington

Is comparative risk assessment an idea whose time has come? Or a political attempt to short-circuit necessarily complex sets of rule-making procedures?

The answer seems to be a bit of each. Professional scientific organisations such as the American Chemical Society are now pushing for comparative risk assessment as a way of rationalising government controls on technological activity, and Congress, responding to industry's demands to lighten the burden of controls, is looking at the type of legislative backing needed to increase its role in the regulatory apparatus.

Congressman Jim Ritter of Pennsylvania, for example, has introduced a Bill that would require the Office of Science and Technology Policy to set up a government-wide mechanism for assessing the comparative risks involved in actions in "scientific, technological and related fields".

The Carter Administration is reluctant to enforce centralised risk assessment as a federal policy. But individual agencies are already giving it increasing prominence within their administrative procedures, accepting that the absolute standards of zero-risk, popular with law-makers in the mid-1970s, may be neither practicable nor scientifically sound.

The push for comparative risk assessment is part of a general drive to restructure the regulatory process by separating the scientific judgment of whether a substance or process poses a health hazard from the administrative judgement of how this hazard, once characterised, should be dealt with.

Not all agree that such a separation is desirable. "The location of a centralised entity for performing comparative risk assessment within OSTP undermines the basic consideration that risk management decisions are social policy decisions which are based only partly on hard science", Dr Nicholas Ashford of the Massachusetts Institute of Technology told the House Science and Technology Committee two weeks ago.

Others, however, including the powerful National Association of Manufacturers, see it as an essential step towards rational regulation. "Before a regulator is faced with deciding how much the public needs to be protected from a substance, he or she should be supplied with an objective assessment of the degree of risk which the substance provides", Dr William J McCarville, Director of Environmental Affairs for Monsanto, told the same committee.

Prompted by such concerns, William Wampler, senior Republican member of the House Agriculture Committee, has introduced another Bill to set up a National

Science Council. This would also operate under the auspices of OSTP, and would be responsible for deciding questions of scientific fact arising from debates on the potential harmfulness of substances involved in food production, decisions which would be binding on all federal agencies.

A similar proposal is being canvassed by the American Industrial Health Council, a body of over 100 chemical companies and trade associations, which wants the National Academy of Sciences to set up a panel of eminent scientists to evaluate the qualitative and quantitative aspects of human chronic health risks associated with all forms of industrial activity.

Neither proposal has yet provoked much enthusiasm within the Administration. But on the question of comparative risk assessment, there is a greater consensus that this should play a more prominent role in decision-making — although reluctance to impose it in a too heavy-handed way, stressing instead the need to build up the research capabilities of the regulatory agencies.

OSTP officials point out that several moves have already been taken in this direction. Two years ago, for example, in issuing an executive order on regulatory reform, President Carter directed that analyses of the costs and benefits of proposed regulation should be prepared before the regulation was introduced.

Furthermore, procedures for standardising the scientific evaluation of hazards across the federal government are being developed by the Interagency Regulatory Liason Group which has already produced a uniform regulatory policy on carcinogens.

But there remains the problem that different agencies have had their legislative mandates written at different times and in different circumstances, giving rise to what OSTP Acting Associate Director Denis Prager describes as a "crucial and necessary" pattern of diversity and pluralism in dealing with technological risks.

The US Department of Agriculture, for example, must observe meat and poultry inspection acts which state unambiguously that no substance, whatever its benefits, may be added to either food if it poses any risk to human health.

Similarly, the Occupational Safety and Health Administration has no legal requirement to take factors other than the safety of workers into account in devising exposure levels to toxic substances (although this could change as the result of an imminent Supreme Court ruling on whether cost-benefit calculations should be taken into account).

Perhaps the greatest push for comparative risk assessment has come in the nuclear field, and in particular over

arguments that base their support for nuclear power on a direct comparison with the health and environmental risks from other energy sources.

At the Environmental Protection Agency, however, which perhaps more than any other agency has had to develop different risk assessment procedures for different types of hazards, there is doubt that comparative risk analysis can be tuned sufficiently finely to meet the needs of specific regulatory situations.

"A comparison of risks within a particular regulatory context may be a useful decision-making tool, and we at EPA are ready to use it as such", Dr Richard Dowd, Chairman of the Agency's Science Advisory board, told the Congressional committee, "but I question how useful it is to go beyond the context of one statute to several statutes, or from one risk situation to a different risk situation."

David Dickson

Research animals

Two bills too many

REGULATIONS to control the use of animals in scientific experiments in Britain are likely to change within the next year or two. Before it took office in April last year, the Conservative Party pledged itself to update the existing legislation, based on the Cruelty to Animals Act of 1876. At the end of last year, Mr Timothy Raison, Minister of State at the Home Office, reaffirmed that intention when he said that the government would like to base the new legislation on the European Convention on laboratory animals, now being drawn up in Strasbourg.

Home Office officials estimate that the European Convention will not be ready until April, 1981. This means that the new UK legislation proposed by the government could not be introduced until the middle of next year at the earliest. Not everyone is prepared to wait that long. Two individual members of parliament — Lord Halsbury and Mr Peter Fry — have prepared their own bills for consideration by the Houses of Lords and Commons respectively. Debates on both bills have been proceeding throughout this session of Parliament.

Lord Halsbury's bill is further than Mr Fry's in the parliamentary process. It received its second reading last October and has just been through several months of scrutiny by a House of Lords select committee. An amended version of the bill, based on the select committee's recommendations, was published last week.

Mr Fry's bill is currently embroiled in debate in a House of Commons standing committee. The committee has so far amended the first six and three quarters of the bill's 38 clauses. At the current rate of amendment the committee will be sitting until August 1982.

Parliamentary procedure, however, will not allow Mr Fry's bill to last that long. It was introduced as a private member's bill and, as such, has to be passed into legislation this session if at all. If it fails to complete the course by late summer, it will have to go back to compete with other private members' bills in the ballot box for the next session.

The Halsbury Bill seems the more likely of the two to survive the parliamentary hurdles. It is also more likely to have the support of the scientific community because it does not advocate prior judgement of the value of scientific research with animals. Its amended form acknowledges and builds on the Protection of Animals Act 1911 but would repeal the Cruelty to Animals Act 1876. The 1911 Act prohibits general cruelty to animals, such as kicking, beating or over-working, and deals specifically with laboratory animals.

In re-drafting Lord Halsbury's Bill, the House of Lords select committee has also produced a report summarising the evidence it has taken and the need for new legislation. The report, which was made available to *Nature* last week, butit is not yet publicly available, says that new legislation is needed because of the great increase in the number of animals used in laboratories over the past century and the greater variety of procedures, not in practice in 1876, to which they may be subject.

Lord Halsbury's Bill follows the 1876 Act in requiring all experimenters with animals to obtain a licence from the Home Office. However, it differs in demanding greater specification by those applying for a licence of the number and type of animals to be used and the procedures to be done on them. Applicants for licences would also be required to state the degree of pain or suffering likely to be experienced by the animal and the measures that would be taken for relieving it.

Lord Halsbury's Bill also incorporates the 'pain' and 'anaesthesia' conditions. These are that an animal that appears to be suffering severely under any procedure must be given immediate relief or be humanely killed, and that animals undergoing procedures which may be expected to cause severe pain or suffering must be properly anaesthetised before the procedure starts,be relieved of any pain afterwards or killed humanely. If this is not feasible it should be humanely killed. The 'pain' and 'anaesthesia' conditions are not written into the 1876 Act, though they have been effectively enforced by the Home Office cruelty to animals inspectorate.

Other points of difference between the 1876 Act and the Halsbury bill concern

● the nature of the sponsors. Both require applicants for licences to have two sponsors; the 1876 Act says that one must be a professor of biology, the other a president of a learned biological society; the Halsbury Bill says that the two sponsors must be chosen from a panel nominated by the Secretary of State.
● the term of licences. The Act allows licences to run indefinitely, the Halsbury Bill for only five years.
● the constitution of an advisory committee. The 1876 Act does not provide for an advisory committee on laboratory animals, although one has been in operation since 1906. The Halsbury Bill would incorporate the advisory committee in the legislation and would give it greater powers than at present. For example, the committee would be required to monitor the extent to which animals are used in painful or stressful procedures, review the possibility of alternatives, and inform the Secretary of State on public opinion. It would also have to consider ethical matters.
● the function of a code of practice. One does exist, although it is not written into the 1876 Act. The Halsbury Bill would incorporate it, increase its status to the equivalent of othe highway code in Britain. Although infringement of the code would not constitute an offence in itself, it could be used as evidence against someone suspected of malpractice.
● batch testing of sera and vaccines. This is not included under the 1876 Act but would be under the Halsbury Bill. Under this provision, the number of procedures notified to the Home Office and the number of licences would increase considerably. Although the idea behind the Halsbury Bill is to include procedures not covered at present, most survey, field, and school work would be exempt. For example, simple injecting of animals or ringing birds would not be included.
● species of animals covered. The 1876 Act covers all vertebrates; the Halsbury Bill would extend protection to chordates and embryos or larvae capable of independent existence.

The Halsbury Bill is also broader in scope than the existing legislation. But it does not specify detail, preferring to leave that to the secretary of state. For example, he would be able to extend the bill to include other species if he chose. He would also appoint the advisory committee.

The amended Halsbury Bill will go to a committee of the whole House of Lords on 20 June. Once it has been through the report stage, it can be presented to the Commons but it is unlikely that the Commons will consider it before next session. It could then be thrown back at the Lords. Although some believe that new legislation could be passed this year, others believe that the government is likely to stick to its plan of seeing the European Convention first.

X-rays

Selling a new source

THE European Science Foundation — normally a quiet body conducting its catalytic business behind the closed doors of committee rooms — is supporting a proposal that Europe should spend £55 million on a new, 5 GeV super-bright European Synchroton Radiation Source (ESRS). Last week at Daresbury, UK, it tried to convince the British synchrotron users that it was right. The result was cautious approval.

Britons are probably the hardest to convince of the case. Their own dedicated source, the SRS, will start producing data at Daresbury later this year, and it will be well ahead of other European sources (*see figure*). Moreover their purse-holder, the Science Research Council, is committed to other large accelerator projects (the Nuclear Structure Facility at Daresbury and the Spallation Neutron Source at the Rutherford Laboratory) up to 1984. And the cash available to run the SRS will only be enough to operate half its beam ports.

The challenge, though, comes from the US. The £12 million National Synchrotron Light Source — a two-stage source under construction at Brookhaven Laboratory, Long Island — will come on line in July 1981 (0.7 GeV) and October 1981 (2.5 GeV). The second stage should exceed the brilliance of the 2 GeV, £5 millions SRS by a factor of ten — giving the SRS just a year as world leader.

So Yves Farge, chairman of the ESF *ad hoc* committee on synchrotron radiation and director of the DCI synchrotron radiation laboratory at Orsay, France, argued last week that Europe will need a more advanced source if it is not to be in the second league. Pressure is also high from countries without access to a national synchrotron source — particularly the Scandinavians, Belgium and The Netherlands — for a European facility to be built.

According to Farge, the Scandinavians — will make the construction of the ESRF a condition of their acceptance of LEP, the next high energy physics accelerator contemplated by the European centre for nuclear research (CERN). The Scandinavian view, says Farge, is that the ESRF should be constructed in the tunnel vacated when the CERN intersecting storage rings (ISR) are shut down as a preliminary to LEP.

Farge is unhappy about that approach, however. There are no biologists at CERN, and one of the attractions of synchrotron radiation is that it is a general tool of structural analysis useful to most disciplines. Biologists, however, would feel isolated at CERN. It would be better, he

feels, to choose a different site and set up a private association to which national research councils could contribute, avoiding the need for complex international agreements. (There is a similar foundation at the Institut Laue Langevin at Grenoble.)

There is also a rapidly increasing interest in synchrotron radiation in industry, Farge believes. DCI at Orsay profited from industrial participation by £5,000 in 1979, and the figure will be £20,000 this year. Oil companies appear to be interested in the routine use of the light to seek out significant trace elements in core samples for oil prospecting; the X-ray intensity available could give them a factor of 1,000 in speed.

However the ESRF itself is a long way from a final design. A sub-group of Farge's committee, headed by Dr D J Thompson of Daresbury, has prepared a preliminary study which defines a 5 GeV, 0.5 Amp, 604 m circumference ring with the brilliance function shown in the figure. Drs B Buras and G V Marr have also defined a shopping list of instrumentation. The machine and building plus half the instruments would cost £55 million at present prices, and could be constructed within 3 to 6 years.

But a new idea has occurred to the committee: that it be an "all-wiggler" machine, a design in which the experimental radiation is taken not from the main bending magnets of the ring, but

from multipole, high field magnets which introduce local high curvature wiggles in the beam path. This would enable the machine to use lower energy and beam current for the same radiation intensity. And the overall radius, as it happens, would be "just right" for the CERN ISR tunnel.

The uses of the ESRF radiation would stretch from molecular biology to nuclear physics, the meeting was told. Using 'undulators' — wigglers with 50-100 poles that produce coherent radiation — spectral brilliances up to seven orders of magnitude greater than those obtainable at DCI are conceivable. Such increases are very rare in science, said Farge, and the consequences are unpredictable.

However Daresbury's Dr Mike Hart, who took the role of the ESRF's chief bubble-burster, claimed one thing is predictable: that such an intensity of radiation from the undulator would destroy most samples. Quick calculations by Farge and Thompson led to estimates of 33-300 Watts onto the sample. "You'll have cooling problems," says Hart.

Probably the most exciting application of the high intensity, coherent light from an undulator would be to illuminate a zone plate X-ray microscope — one that depends on diffraction effects to produce focusing and de-focusing equivalent to the lenses of an ordinary light microscope. This application is limited by the fineness

with which zone plates can be drawn, but object resolutions of 100 Angstroms are foreseeable; and with a wavelength of 25 A, tuned to detect carbon but not oxygen, the prospect opens of following ultrastructural movements in live cells.

Nevertheless the ESF has not argued the case sufficiently for the ESRF as against existing synchrotron light sources, says Hart; 70% of the arguments used in the ESF document "the scientific case" for the ESRF apply to synchrotron radiation in general, and not to the ESRF in particular. The document will have to be rewritten in two years' time, Farge admits.

Robert Walgate

Four documents on the ESRF are available from the European Science Foundation, 1 quai Lezay-Marnesia, F-67000 Strasbourg, France: 'The Feasibility Study', 'The Scientific Case', 'The Machine', and 'Instrumentation'.

Training

Thoughts from the think tank

THE British government's own think tank, known as the Central Policy Review Staff (CPRS), published last week a mildly subversive prescription for making the products of the British educational system more suited to what is called "the world of work". The CPRS report ("Education, Training and Industrial Performance", HMSO, £4.25) gives no explanation of how it came to be published or even written.

Among the points at which the recommendations of the report may seem at odds with current government policy, the following are conspicuous:

• There should be formal standards and qualifications for skills acquired by means of vocational training.

• The government should continue to provide vocational training for young unskilled workers.

• More attention should be paid, especially in the age range 16-18, to the acquisition of practical skills, preferably in colleges of further education, not schools.

The CPRS does however accord with current government policy in its advocacy of a core curriculum (consisting of English, mathematics, science, a practical subject and "possibly" a foreign language) in the age range 11-16. The report also asks that the financing of further education by public loans should be reconsidered.

The CPRS is suitably modest in its acknowledgement of how little is known of the relationship between education training of any kind and the eventual benefits to employers and the national economy. There is no single issue on which a government initiative would, in the CPRS's judgment, make training radically more effective — and, even if there were, implementation would be hampered by the

WAVELENGTH (Å)
Spectral brilliance (in photons s⁻¹ mm⁻²mrad in 0.1% bandwidth) is compared for the proposed ESRF, the Brookhaven NSLS (ready October 1981), the Daresbury SRS (October 1980), and the Frascati ADONE, the Hamburg DORIS and the Orsay DCI (in operation).

decentralisation of the British educational system.

Some of the ironies of the British educational system are however neatly described by the report, which is based on an unsystematic survey of the opinions of educational and other organisations and on the CPRS's own views. One large company is quoted as holding the view that university science courses are "too academic" but nevertheless choosing to recruit graduates from the same academic courses in the belief that these would have attracted the most able students.

In its assessment of the provision of education and training, the CPRS echoes the conventional wisdom that Britain is better supplied with means of initial education and training than with facilities for continuing education and retraining.

The report has few concrete suggestions for the improvement of continuing education in Britain. It remarks that elsewhere than in the United Kingdom, and especially in the United States, continuing education flourishes because people acquiring extra qualifications are often rewarded with extra pay, and notes regretfully that "pay policy and union pressure" have prevented such incentives emerging in the United Kingdom. It therefore pins its hope for the future on part-time and evening study.

The more controversial recommendations are, predictably, those that affect the pattern of school education in the United Kingdom. The CPRS comes to the same conclusion as the Secretary of State for Education and Science, Mr Mark Carlisle, that there should be a core curriculum in the age range 11-16 but that this should be adopted voluntarily by educational authorities and not centrally imposed by Act of Parliament. (The report notes that the only present legal compulsion, the requirement that religious knowledge should be taught in schools, "has not been notably successful".)

The CPRS also wants there to be a more deliberate concern by those who design school curricula for the needs of industry (and is explicitly critical of the School Mathematics Project, now widely used in British schools, for its failure to consult with industry).

On the shortage of science and mathematics teachers in British schools, the report asks that the government should "grasp the nettle" of paying teachers with special skills more than teachers of other subjects. The report does not refer to the longstanding opposition of the teachers' unions to proposals of this kind.

The CPRS also has views about the way in which academics in British higher education should be paid. It refers in its report to the system in the United States under which some academics are paid for only nine months in each year, but are free to take paid employment elsewhere (or to carry out research) in the remaining months.

The CPRS is especially attracted by the way in which this practice may give some academics first-hand experience of industry, and asks that the Department of Education and the University Grants Committee should consider the problem and "use their influence" to get rid of existing restrictions. It hazards no guess at the salary levels that would be established after such a reorganisation. ☐

Three Mile Island

Reactor entry bid aborted

AN attempt by two Metropolitan Edison engineers to enter the contaminated containment dome of the damaged Three Mile Island reactor was abandoned last Tuesday (20 May) soon after 9.00 am when the inner door of an airlock refused to open. The engineers made three attempts to open the 3″ thick steel door leading into the containment dome by the normal procedure of giving the wheel of the door a three quarter turn and pushing. After a total of 11 minutes of the planned 15 minute "mission", the men were recalled by radio. A total of 10 millicuries of krypton-85 was vented to the atmosphere during the procedure and the engineers received a whole body radiation dose of 10 to 15 mrem.

Officials from Metropolitan Edison in Middletown, Pennsylvania, and General Public Utilities in Parsippany, New Jersey, said that further attempts to enter the dome would be postponed "indefinitely", until the situation could be analysed further. "We have only one theory" said Sandy Solon of Metropolitan Edison. "Corrosion, either around the hinges or around the door seals, is causing the door to stick". The airlock door is made to close tolerance and has not been opened for 14 months.

By noting which instruments inside the dome have not been operating, engineers have estimated that the dome is flooded to a depth of seven feet, "plus or minus one or two per cent". The airlock door is 20 feet above the floor so "there is no danger of a release of radioactive water into the airlock." Video monitors show a steady mist is falling inside the dome as heat from the reactor (which is still at 200°F) causes water on the dome floor to evaporate, rise to the ceiling and condense. "The atmosphere inside is highly corrosive, to say the least" said Bill Murray of GPU.

The presence of corrosion in the door "bodes ill" for the functioning of ventilation equipment inside required to cool the dome and maintain a negative pressure with respect to the outside to minimise the possibility of leaks. Engineers have rejected the possibility of forcing the door with hydraulic jacks for fear of tearing the polyplastic inflatable door seals. A failure of the air-lock door to reseal might necessitate the uncontrolled venting of the 57,000 curies of krypton-85 still trapped in the dome. Bill Murray of GPU said that the Nuclear Regulatory Commission may give the plant operators permission to make a controlled release of the radioactive gas to the atmosphere, thus

Three Mile Island reactor — which way back in?

permitting a forced entry. "Hundreds of thousands of curies have already been released with no ill effect. We hope the NRC will let us vent with maximum controlled dispersion and we can then reassess the situation." Non-gaseous isotopes such as Sr-90 and Cs-137 are presumed to be precipitated on the walls of the dome or trapped chemically in the ventilation filtering system.

The purpose of the attempted 15-minute entry was to monitor radiation in the dome, estimated to be 3 rem per hour of gamma radiation and 200-300 rem per hour of beta radiation. The engineers were also to check for radiation hot spots, examine the ventilation and cooling systems, check for structural damage and take "swipe samples" with gauze of radioactive residues on the walls and stairwells for detailed isotopic analysis.
The two engineers, Michael Benson, aged 27, a nuclear engineer employed at Three Mile Island since 1974, and William H. Berhle, aged 36, a project engineer employed there since 1967, were two of several volunteers. They were fitted with Viking dry diving suits (heavy rubber suits of the type used by helmeted deep sea divers) covered by the standard yellow anti-contaminant radiation protective plastic clothing. Breathing apparatus was a Scott airpack of the type used by US firefighters with a 30-minute air supply. The men practised for two months on the identical airlock of the second Three Mile Island reactor.

Tuesday's failure was the second abortive attempt to enter the building. A previously scheduled entry on 24 April had to be cancelled when it was discovered that modifications in the breathing apparatus prepared by the Bio Marine company had not been submitted to the National Institute of Occupational Safety and Health for approval. At a press conference on 21 May, Benson and Berhle said they were "disappointed" and would volunteer again. The GPU said it would announce its next move "within a week".

Joe Schwartz

Recombinant DNA

Guidelines for scale-up

Washington

Like a man with a new pair of shoes, the US National Institutes of Health are experiencing some discomfort in administering industry's voluntary compliance with the safety guidelines covering recombinant DNA research.

Pressures on the NIH are coming from two directions. On the one hand, increasing competition from European and Japanese industry is leading US companies to complain that lengthy procedures for approving new host/vector systems and large-scale fermentation experiments are becoming a commercial handicap.

On the other, the members of the NIH's Recombinant DNA Advisory Commission are feeling their way uncertainly into the engineering and safety aspects of large-scale fermentation techniques of which few possess either detailed knowledge or expertise.

The system of voluntary compliance was proposed last year by NIH Director Dr Donald Fredrickson, largely as a way of avoiding the need for new legislation extending the guidelines to the private sector. Since the system was introduced in January, eleven companies have registered their Institutional Biohazard Committees (IBCS) with the NIH, and seven large-scale experiments have been approved.

Last year the containment guidelines were reduced for most experiments to a level requiring minimal physical safeguards, with the result that few companies now feel them to be excessively restrictive. Indeed some take comfort from the fact that Japan has recently introduced the NIH guidelines in their original, more stringent, form.

There is greater concern, however, about the time taken up by NIH's certification procedures, in particular that required to review new host/vector systems — a responsibility which many RAC members now consider to be one of the committee's most important functions.

At present, for example, the disabled bacterium strain *Escherichia coli* K-12 is the only approved host/vector system for experiments at the P1 minimum containment level (although the use of *Saccharomyces cerevisiae* strain of yeast is expected to be recommended for approval at RAC's next meeting).

The result, according to Dr Peter Farley, President of the Berkeley-based Cetus Corporation, is that European companies who can locate their operations in countries with minimal certification requirements already have a major commercial advantage through being able to exploit other host/vector systems, such as *Bacillus subtilis*.

Time is also being taken up by the need for special approval by the Director of NIH for each experiment carried out using more than 10 litres of culture — a relatively arbitrary limit set in the early days of the guidelines and apparently based on conventional laboratory practices.

Amendments to the guidelines which would accelerate the approval process for commercial developments have now been recommended to NIH by Dr Irving Johnson, Vice-President of Research for Eli Lilly and Company, which has already received permission for several scaled-up experiments in the production of human insulin.

In particular, Dr Johnson is proposing that, once approval has been given for a particular experiment to be carried out above the ten-litre limit, further volume increases using the same biological materials at the same containment levels would require merely to be approved by the local IBC.

More controversial is Dr Johnson's suggestion that, in order to make up for RAC members' lack of experience with large-scale applications, industry representatives should be added to the committee with expertise in areas such as fermentation technology and engineering.

And he is also proposing that a permanent subcommittee be set up to advise the Director of NIH on actions related to large-scale applications, with authority to recommend approval of preliminary plans for large-scale operational facilities.

The various proposals will be discussed by the RAC when it meets next week. Their reception is uncertain.

Committee members are aware that they lack expertise in either worker safety or fermentation engineering. "Many have not been entirely happy with their role" says committee member Dr David Baltimore of the Massachusetts Institute of Technology.

Yet there is disagreement over whether this lack should be made up primarily by expanding the scope of the committee, through increased use of consultants or the addition of new members. Or, alternatively, whether greater involvement should be encouraged from agencies which already have statutory responsibility for such matters, in particular the Department of Labor's Occupational Safety and Health Administration.

Either way, it seems increasingly unlikely that there will be new legislation imposing

the guidelines on the private sector. A bill seeking to do so, and requiring the registration of all industrial activities using recombinant DNA techniques, has been introduced by Senator Adla Stevenson Jr; but it has so far failed to gain any significant support, either inside Congress or without.   **David Dickson**

Comecon Science
High T, Low K

A NEW Comecon International Laboratory of High Magnetic Fields and Low Temperatures is to be built in Wroclaw during the next Five Year Plan (1971-1985) by the Academies of Science of Poland, Bulgaria, the Soviet Union and East Germany, with possible participation also by Czechoslovakia. This will replace the existing somewhat cramped premises which have served the laboratory since 1968.

According to Dr Wlodzimierz Trzebiatowski, until recently the Director of the Laboratory, and who still, in retirement, takes a keen personal interest in it, Wroclaw was originally chosen as the site of the laboratory for a number of practical reasons. First the Polish Academy of Sciences already had a flourishing Institute of Low Temperature and Structure Research in Wroclaw. Wroclaw is near the important East German science centres of Dresden and Berlin, and helium, essential for low temperature work, is available from a Polish extraction plant only 100 km away. Finally, just as the laboratory was being planned, the Lower Sjleskan electricity board, was installing new generators in the Wroclaw tramway substation and was willing to donate the old generators to the Academy of Science.

The present laboratory is concerned with such things as the properties of hard semiconductors, new magnetic materials and the measurement of specific heats below 1°K. Cooling below 4.2°K is effected by helium cooling in the field of superconducting magnets of 5T and 15T, and work is in progress on adiabatic demagnetization of nuclear and electron paramagnetics, allowing temperatures below 0.1 K to be attained.

The laboratory has a special interest in compounds of uranium with non-metals of the Vb and VIb groups — a speciality begun by Professor Trzebiatowski at the Low Temperature Institute of the Academy of Sciences in the early 1950s. (Since his initial discovery of ferromagnetic transition in uranium hydride UH_3, some fifty such uranium compounds, mostly chalcogenides, have been discovered there.) One new project, of especial interest to Dr Evgeni Leyarovski, of the Bulgarian Academy of Sciences, who was Deputy Director of the Wroclaw Laboratory from 1974-1977, is the study of superconductors
Tramway generators keep turning in Wroclaw

with magnetic impurities. Research on this phenomenon is also going forward in Sofia, but even with their new 5 tesla superconducting magnets installed this spring, the Bulgarians will still have to do much of their work in Wroclaw.

Nevertheless, even Wroclaw cannot at present offer the facilities which an international Comecon laboratory needs. Far more laboratory space is required, and, more important, the ex-tramway generators can operate only one of the three magnets at a time, so that the various teams often have to queue for "magnetic time". The new site, on the banks of the Odra, will provide space and facilities for more magnets with higher fields as well as an ample supply of water for cooling the electromagnets.   **Vera Rich**

Soviet oil
No real shortage

THE Soviet Union has initiated a major change in its method of estimating oil production costs which will result in a dramatic increase in production from proven fields, says a report* published last week by PetroStudies, a Swedish group specialising in the analysis of the Soviet oil and gas industry. The report disagrees sharply with CIA forecasts that the Soviet Union will suffer a shortfall in oil production. The CIA prediction has been used repeatedly in recent months by US oil officials to suggest that a Soviet oil shortage was leading it to have a material

"Try not to be long"

interest in controlling the Middle East.

The PetroStudies group finds that a recent 11-20 fold rise in the reference price of oil, from $0.75 — $1.50 to $17 — $20 per barrel, will correct the "systematic underexploitation of Soviet oilfields over the past thirty years". The reference price is the figure planners use to assess the cost of opening new oil fields, compared with the cost of intensively developing existing ones. The higher reference price represents a recognition by Soviet planners that development of new oil fields has created unacceptable pressures on capital, labour and material, necessitating a new economic approach to oil development. The PetroStudies report says that the new

policy means that "there is no danger whatsoever that the USSR will be forced to become a net importer of oil this decade and highly improbable that it will become so in the 1990s".

An additional feature of the new policy will be a decline in Soviet imports of American oilfield machinery, the report says. Intensive mining of existing fields by many wells will substitute for high capacity pumping from a few wells, a policy which will significantly decrease Soviet dependence on US-produced high capacity oil pumps.

According to the *International Herald Tribune*, diplomatic sources have suggested that the PetroStudies' findings

may be "part of a Soviet campaign of disinformation". M Jermol of PetroStudies explained that their analysis is based on original Soviet sources obtained though normal institutional channels. The materials include Russian texts of official oil industry documents, specialised books and journal articles, reports from Soviet research institutes, and petroleum conferences, extending back over ten years. "It would be impossible to base a report like this on a few privileged documents" said Jermol.

Instruments

New homes for old instruments

Is Britain's scientific heritage being ignored and forgotten by its museums? Arthur Frank, a collector of scientific instruments, believes that it is. About half of his collection of instruments dating from the early eighteenth century, which runs into thousands, has been placed in British museums — mainly central museums in London and Edinburgh. But the other half is on display only in his garage in Jersey, while Mr Frank searches for more conventional homes, so far with little success.

There are more than 1,100 museums in Great Britain and Ireland, but Mr Frank says that fewer than a dozen of them take scientific instruments seriously. But they do appear to differ in their reactions. Some have bought or borrowed instruments from Mr Frank. Others have declined to do so either on the grounds that the instruments which he has available would not fit in well with existing collections or because they would not be able to afford the prices asked. But many, mainly provincial museums, have said that they are the wrong organisation to approach because they do not have the expertise to judge scientific instruments.

One of the few provincial museums to house part of the Frank collection, however, is the Museum and Art Gallery, Doncaster, Yorkshire. Mr J Barwick, the museum's director, had to draw on outside expertise to mount the exhibition. His interest in the Frank collection stemmed from his wish to display a selection of early mining and surveying instruments appropriate to an old mining and engineering town; the public response has now persuaded him also to borrow some of Mr Frank's microscopes and astronomical instruments and he is planning to extend this section of the museum.

Doncaster Museum's special interests may be exceptional. Elsewhere, according to one official, regional and municipal museums are likely to be more interested in a display of instruments representative of different types than of a specialist sub-collection from Mr Frank's garage.

Mr Frank, nevertheless, is determined that his instruments should not be disposed of one by one. He also requires that recipients of objects from his collection should catalogue the instruments and put them all on display. He says that he is prepared to make gifts of them, lend them for twenty-one years, or sell them at two-thirds of the estimated value, dealing with learned societies as well as museums. One snag that may deter some museums is that Mr Frank's valuations seem high.

So far, the large specialist and national museums have been the chief recipients either loaning the instruments or more usually buying them under the two thirds

of value offer. The Science Museum in London has about 1,500 of his cameras and accessories, and there is a permanent exhibition of field and opera glasses and of prismatic binoculars. Inevitably, however, such a museum is primarily concerned to fill gaps in its present collection.

Elsewhere in Britain, the Royal Scottish Museum in Edinburgh has a display showing the development of the achromatic microscope in the formative years 1800-1860 (and is also negotiating for the remaining Scottish instruments in the Frank collection). There is also a collection of astronomical and terrestrial telescopes at the Royal Observatory, Edinburgh.

The parts of the Frank collection not yet disposed of are strong on spectroscopic and stereoscopic devices, as well as early spectacles. He is especially proud of his Marshall microscope (*circa* 1700) and his Ramsden astronomical instruments from the late 1700s.

CORRESPONDENCE

Parkinsonian exasperation

SIR, — Further to Robert Moss' letter (1 May, p9,) it is of interest to consider the size of a primitive group of workers when liaison begins to become less effective and an administrator is appointed. Following Parkinson's work on committees (C N Parkinson, *Parkinson's Law*, 1958), experimental evidence from both scientific and socio-political groups seems to indicate that communication remains viable for groups of between 5 to 11, with an optimum of 7 to 9. Between 12 and 14 members, a part-time administrator is usually appointed, and the stage is set for the entry of centralisation.

One of the finest examples of misgrouping to be seen in public was the three day meeting between management and union staff, shown recently on BBC 1. Possibly unaware of Parkinson's work, the two scientists who convened the meeting set up a group of approximately 21 to 23 people, with predictable results. Despite the efforts on both sides to overcome the traditional divisions between management and unions, the lack of communication due to the group size increased exasperation to the point when people began to leave. Amazed by the rising irritation, the scientists sought to alleviate it by altering the seating arrangements (*vide* Parkinson on the shape and size of committee tables). Communication was restored only when the participants spontaneously divided into two groups of 10 to 12 each, both containing managers and unionists. It was difficult to determine who generated this split, given the highly condensed version of events presented, but it was certainly not the scientists. Additional information to confirm or deny the hypothesis that smaller groups were suggested by the women trade unionists would be welcome.

Stage 3 of Parkinson's progression is considered by Moss to produce an 'intolerable' workload on the administrator, when he is burdened by 17 lines of communication

$(L_{wi} + L_{ai})$. The above empirical analysis suggests that the maximum tolerable number of $L_{wi} + L_{ai}$ will be of the order of 10 to 12.

Yours faithfully,

B M GRAY

Climatic Research Unit,
University of East Anglia,
Norwich, UK.

Feminist speculation

SIR,—The thought-provoking discussion of the reasons why increased centralization is accompanied by decreased effectiveness presented by Robert Moss was both perceptive and pertinent. I should like to comment on an aspect which Dr. Moss appears to have overlooked. He states that the results of one study showed that "the production of scientific papers per man decreased as the organization increased in size." Was the production of scientific papers by women not affected? If not, what are the most likely reasons? Can one assume that women are less likely than men to be affected by this extension of Parkinson's Law?

The administrators described by Dr. Moss were apparently male, and it would be interesting to speculate on the outcome had some or all of the administrators been female.

Yours faithfully,

C RIGBY

Aylmer,
Quebec, Canada.

Erratum

In Robert Moss's letter, "Expanding on Parkinson's Law" (1 May) there was a typographical error. In stage four of his administrators' model, the equation $l_{wi} = W$ erroneously appeared as $l_{wi} = W^2 + A$.

Editor, Nature.

Smallpox and conservation

SIR, — It has been announced by the World Health Organization that smallpox now has been eliminated. The virus responsible for smallpox, an organism formerly abundant and widespread, has been systematically, deliberately, and (as it appears) completely eradicated from all the natural systems of the world. With the exception of samples in a few laboratory 'zoos', it is extinct.

Those responsible for the demise of smallpox will be praised universally, I am sure. But what an eloquent dilemma this presents to conservationists.

Statements of the conservation ethic normally include such clauses as "the preservation of species diversity" and "the protection of endangered species". What happens to those ideals in the aftermath of smallpox? Does the conservation ethic inevitably reduce to a pragmatic formula for the protection of the human species, or to a sentimental affection for the cute and the cuddly? Would anyone care to provide a satisfactory statement of what we really do mean when we speak with solemn and genuine concern about the protection of the natural world?

Yours faithfully,

JOHN MIDDLETON,

Carleton University,
Ottawa, Canada.

Making books cheaper

SIR,—Your editorial, "Are Books Too Expensive?" (24 April) is a reasonable and most welcome voice in the discussion of rising book prices. At The University of Chicago Press we have been giving a good deal of thought to measures that would decrease the costs of book production and therefore reduce the list price. These include: the publication of more original paperback books; printing some books from camera-ready typescript rather than setting all books in type; asking authors to forego some portion or royalty on the sale of a specified number of copies of books with smaller audiences; and simply not publishing certain classes of books such as the proceedings of symposia because their relevance is commonly limited over time.

The cooperation of those who write, distribute, review, and purchase books is essential to the success of any of these measures. Many scholars prefer to purchase paper-bound books or books that are printed from typescript because they are less expensive. Yet these same scholars baulk at the prospect that their own books might be published in such a fashion, chiefly because their colleagues see such methods as characteristic of "second-rate" work or treatment. Some scholarly journals still refuse to review original paperbacks, and some libraries still refuse to buy them.

We as publishers must recognize that what is in the book must reach the intended audience and that the costs of "traditional" production may force the price of a book beyond the means of at least a fair proportion of the audience, particularly those who are students or younger faculty members, but we need and appreciate the cooperation of both authors and readers.

Yours faithfully,

SUSAN E. ABRAMS

University of Chicago Press

NEWS AND VIEWS

Evolutionary genetics of snails

from J. S. Jones

MOLLUSCS are very suitable for research into evolutionary genetics. They are sluggish (and hence easy to capture and to mark), are common in a variety of habitats, and often display a striking shell polymorphism.

Many evolutionary mechanisms are now known to affect shell polymorphism in the European snail *Cepaea nemoralis*. Their importance varies greatly from population to population and the realisation that the factors influencing even this simple system are very complex is perhaps the most important point gained from the fifty years for which it has been studied.

At a recent conference* M. Lamotte (Ecole Normale Superieure, Paris) discussed the controversy between himself and A. J. Cain and the late P. M. Sheppard (University of Liverpool); this has often been misrepresented as a conflict between mutually exclusive mechanisms of visual selection by predators, of climatic selection and (in some populations) of genetic drift. However, it is now clear that to explain gene frequencies in individual populations it is usually necessary to produce complex explanations involving several evolutionary forces (for a recent review see *Ann. Rev. Ecol. Syst.* **8**, 109; 1977). This complexity probably applies also to the evolutionary biology of other polymorphisms (such as those at loci controlling soluble enzymes) but, as less information is available for most of these, there is still a tendency to search for single, unifying explanations of their existence. Climatic selection is generally accepted to affect gene frequencies in *Cepaea;* S. M. Tilling (North London Polytechnic) showed that different natural and artificial (black or white painted) morphs have behavioural differences which are related to their energy uptake in sunshine. *C. nemoralis* populations living in complex environments have more shell polymorphism than do those from habitats in which most individuals experience the same climatic stress, and experiments with snails marked with spots of dye which fade at a known rate when exposed to the sun suggest that populations exposed to a variety of climatic stresses are indeed more variable than are those with a narrower niche (J. S. Jones & R. F. Probert, University College, London).

Natural selection is also involved in the leucine amino-peptidase polymorphism of the mussel *Mytilus edulis* according to R.K. Koehn (State University of New York). In Long Island Sound a steep cline in allele frequency coincides with a salinity gradient. Each year the cline is displaced to a varying extent by the immigration of oceanic larvae, but each year selective mortality ensures that it returns to the same point.

Historical effects — whose role in the evolution of molecular polymorphism is notoriously difficult to assess — also influence the present-day distribution of shell variation in some *Cepaea* populations. Information from old records on the land use patterns of downland in southern England suggests that some local anomalies in gene frequency result from the spread of populations from woods into open habitats which become available to *Cepaea* only when sheep grazing declined (R.A.D. Cameron, Birmingham University; M. A. Carter, Portsmouth Polytechnic). Changes in gene frequency over the past 20 years in a *C. hortensis* population on the earthwork of Silbury Hill are also correlated with vegetational changes, in this case resulting from increased human usage. The intensity of selection is as much as 10% per generation (S. Wall & M.A. Carter; Portsmouth Polytechnic; B. C. Clarke, Nottingham University). These rapid evolutionary changes are a microcosm of the long-term changes in gene frequencies in English *Cepaea* shown from shells found in archaeological sites by A.J. Cain.

All theories of the origin of species depend on historical events which are by their nature not directly testable. M. J. D. White has recently put forward *(Modes of Speciation* W. H. Freeman, San Francisco; 1978) a theory of 'area effect speciation'. This arises directly from the observation by Cain and Currey *(Phil Trans. Roy. Soc. Lond. Ser. B.* **246**; 1; 1963) of 'area effects' in *Cepaea*. In many places large regions of constancy of allele frequency for shell polymorphism are separated by steep clines (which usually do not coincide with an obvious environmental discontinuity) from adjacent areas in which the *Cepaea* populations have very different allele frequencies. White suggests that each area effect is a marker for a reorganisation of the whole genome and that a slight reinforcement of this could lead to speciation within a continuous population,

without the complete geographic isolation necessary in Darwin's model. This theory adds new interest to studies of genetic differentiation in snails. One prediction might be that if adjacent area effects have diverged at many loci, some of these might be detected by enzyme electrophoresis (as is the case in incipient species of Drosophila). R. K. Selander and colleagues (University of Rochester, NY) find no evidence for parallel genetic differentiation at the morphological and the molecular level in some striking area effects in *C. nemoralis* in the Pyrenees. The pattern of distribution of species of the snail *Partula* on the Pacific island of Moorea does suggest that they have arisen as a result of the divergence of adjacent populations. B. C. Clarke and J. J. Murray showed that at some species' borders there are localised hybrid zones between populations which elsewhere act as good species, whilst in one locality there is a 'ring-species' complex with a diameter of only 3 km. Although area effect speciation might indeed be involved here, different species of *Partula* — even those from islands thousands of kilometres apart — show only slight differences in the frequencies of genes controlling molecular polymorphism. The same is true of morphologically distinct species in the freshwater genus *Elliptio* (G. M. Davis, Academy of Natural Sciences, Philadelphia). *C. nemoralis* populations do show genetic structure at the molecular level but this is independent of the area effects themselves. Pyrenean populations assort into several geographically and genetically distinct groups on a factorial analysis of enzyme and shell polymorphism, and there may also be pericentric inversion differences (which could act as isolating mechanisms) between populations of this species (C. Page, North London Polytechnic). However, area effect speciation could scarcely have occurred in the genus *Cepaea,* which has only four species but thousands of area effects.

The lack of concordance of polymorphism in the genes controlling enzyme structure with other indicators of species divergence suggests that other loci — such as regulator genes — might be involved in speciation (Wilson, Maxson & Sarich *Proc.*

J. S. Jones is in the Department of Genetics and Biometry, University College, London.

natn. Acad. Sci. U.S.A. **71**, 2843; 1974). The importance of ontogenetic and regulatory effects in molluscan population genetics is emphasised by the work of J. Heller (Hebrew University of Jerusalem) on the Israeli snail *Xeropicta,* an annual species. Adult *Xeropicta* in the mountains are dark coloured, those in the coastal plain pale. As the mean annual temperature is higher in the plain than in the mountains, this accords with the common poikilotherm pattern in which populations from hot places have a higher reflectivity of solar radiation than do those from cool. However, there are great annual fluctuations in temperature in Israel, and in the summer the snails are under extreme solar stress. They adjust their shell reflectivity to ensure that they absorb the requisite energy from the sun during the brief growing season, but are protected from excessive heat at other times; in the mountains they are born pale and become darker, while in the plain they are born pale but become paler. The structural genes controlling shell polymorphism are expressed only at the correct period of the life cycle. Ontogenetic effects are also found in the Caribbean snail *Cerion* (S. J. Gould, Harvard; D. Woodruff, University of California, San Diego). This genus shows a great variety of morphological types. Simulation of the growth process shows that simple alterations of the growth rate early in development can lead to startling differences in adult shell form. Developmental plasticity (perhaps promoted by polymorphism in the genes regulating growth rate) allows each species to attain a multiplicity of adult forms attuned to particular habitats. This may allow a single species of *Cerion* to fill the ecological niches occupied by several species of mollusc on dunes in southern Europe.

Molluscs show a range of sexual strategies from complete outcrossing to obligate parthenogenesis. They are therefore useful in research on the evolution of sex, particularly as the degree of outcrossing can be estimated from the zygotic proportions at loci controlling protein polymorphism. G. McCracken (University of Tennessee) and R. K. Selander discussed the European slugs which have colonised the US. There is great variation in the degree of outcrossing, with some species adopting a mixed strategy of sexual and asexual reproduction. Measurement of the niche breadth of several species on an ecologically well-characterised experimental plot shows that the three species with the broadest niche are present as monogenic and asexual strains. This is hard to reconcile with models which predict that sexual species have more evolutionary flexibility than do asexual.

The conference demonstrated that although the single helix of the snail's shell may be less central to modern genetics than the double helix, it continues to provide important tests of evolutionary theories. □

100 years ago

A proposal has been set on foot for lighting the Sheldonian Theatre, Oxford, and the Camera of the Radcliffe Library with the electric light. It has long been regretted by many members of the University that the Sheldonian Theatre is not available in the evening for any purposes of public interest, however great, for want of lighting. The neighbourhood of the Bodleian Library has, however, been a bar to any proposal for lighting by means of gas or any ordinary method. The care with which the heating apparatus of the Theatre has been inclosed within a fire-proof chamber is sufficient evidence of the importance attached by the curators of the Theatre to absolute security in this respect. The development of the electric light has now rendered it possible to illuminate public rooms by a process absolutely free from danger of fire. It has been adopted largely in the reading-rooms of our public libraries, and notably in the reading-room of the British Museum.

Herr Zehfuss has lately given (*Wied. Ann.,* 4) some personal experiences of the phenomenon of "after images of motion". These after images may be had, *e.g.,* in a train, if one look at a point on the horizon for a little, then turn to look at (say) a horizontal fibre in the wood of the carriage, or close one's eyes. Motions then seem to be still perceived; in the latter case, *e.g.,* a stream of sparks seems to be moving to the right (or if the point originally looked at have been between the observer and the horizon, there is a stream of sparks above going to the right and one below to the left). Herr Zehfuss offers a physiological explanation, in preference to the partly psychical ones proposed by Plateau and Oppel. Each individual nerve rod, he supposes, has special blood-vessels, which, when the original image of a moved object goes to the right, directs the course of the blood to that side, just as in ordinary light the decomposed blood is promptly replaced by fresh. By this preponderant direction of blood to the right a heaping up occurs in each retinal element on the right, which gives rise to return currents as soon as the outer cause has ceased to act. As the blood flows back there arise, in consequence of the specific excitability of the rods, those spark-streams, which are projected as elementary motions to the right.

High-resolution imaging of laser-driven implosions

from Lynn R. Veeser

HIGH-RESOLUTION imaging of the radiation (mainly electrons, neutrons, X-rays, and alpha-particles) emitted by laser-driven DT fusion implosions is difficult because such radiation cannot easily be focused. Nevertheless, imaging could be an extremely useful diagnostic tool, especially for comparison with the extensive computer modelling now being carried out for laser-fusion compressions. Neutron imaging has not been achieved because the fluxes are small and the efficiency for detecting neutrons is low. Electrons are generally affected by the strong electric and magnetic fields in the laser plasma but X-rays and, if the fields are not too strong, alpha particles, can be imaged by pinhole cameras.

Unfortunately, to produce a high-resolution image, a pinhole camera must have a tiny aperture and this will cause low sensitivity. If additional signal strength is needed it is necessary to use more than one aperture. The resulting image, or shadowgraph, is a superposition of the images from all the apertures, and it is not useful or recognizable unless a real image of the source, similar to that seen for a single aperture, can be reconstructed from it. The two-step process by which this imaging and the subsequent reconstruction are done is known as coded-aperture imaging.

Coded-aperture imaging has been used by astronomers for a number of years to image X-ray stars, and it is employed in the field of nuclear medicine to enhance the signal-to-noise ratio and the resolution in radiographing body organs; but, because of the difficulties involved in fabricating the complicated microscopic apertures needed for ultra-high resolution, its application to laser plasma has been delayed for some time. Recently, however, groups from the US laser fusion laboratories at Livermore and Los Alamos have reported the use of coded-aperture techniques in imaging of imploding laser-driven fusion targets.

Ceglio and Larsen (*Phys. Rev. Lett.* **44**, 579; 1980) used a Fresnel zone plate (in this case a series of concentric gold rings with radially decreasing apertures and held together by thin struts) as a coded aperture to measure the X-rays from a thin glass microballoon which had been filled with DT fuel and irradiated with about 20 TW of laser power. They obtained X-ray images from the shadowgraphs by optical reconstruction; each shadowgraph was illuminated with a coherent light source, much as is done in holography, producing a magnified image of the initial source. The experiments were done at the Shiva laser facility of the Lawrence Livermore Laboratory.

When a high-power laser pulse strikes a target surface, it generates a plasma which includes a significant number of high-energy (suprathermal) electrons. The

target, consisting of fuel contained in a thin-shell microballoon known as an exploding pusher, implodes when these hot electrons heat the shell, causing it to explode both inward and outward; the inward momentum compressing the fuel. In the Shiva experiment two simultaneous short (typically < 100 ps) laser pulses, each of about equal energy, imploded the shell from opposite points (the poles). X-rays from the implosion were imaged in three energy intervals by stacking layers of X-ray film and filters. Two of the spectra were of great interest. Thermal X-rays (from 4 to 7 keV) were found near the inner part of the imploding shell and are thought to represent the hottest part of the pusher material at a time when its diameter was nearly at its minimum. Two disk-shaped regions, about 40 μm apart and clearly visible in the reconstructed radiograph, showed the pusher temperature to be hottest at the poles. Relatively few X-rays originated at the target center in the region of the compressed DT fuel. Of perhaps even greater interest was an image of the suprathermal X-rays, or bremsstrahlung, derived from interactions of the hot electrons with ions from the exploding pusher. If the hot electron distribution is assumed to be uniform, i.e., if the electron ranges are long compared to most spatial nonuniformities in their production, then a measurement of the bremsstrahlung distribution should map out the ion distribution during the early stages of the implosion. The suprathermal X-ray image (from 17 to 30 KeV) published by Ceglio and Larsen shows a hollow shell of nearly the same outer diameter, about 300μm, as the initial shell, but the X-ray density was much more intense near the poles than the equator.

The general shapes of these X-ray images, including the decrease in intensity near the equator, were matched nicely by numerical simulations. Having experimental pictures to compare with the simulations has made it possible to test the importance of various proposed energy absorption and transport mechanisms in the target. The quality of the agreement provides considerable satisfaction with the present state of numerical laser-fusion calculations.

Two features of the measurement are not found in the simulation, however. A number of ripples appear on both the inside and the outside of the X-ray shell structure, and the authors attribute the ripples to nonuniformities, or hot spots, in the laser focus. In addition, one larger protuberance, perhaps 100 μm in size, was seen on the inner side of the shell. It seems likely that this protrusion is an indication of breakup of the pusher shell occurring during the laser pulse.

In a previous experiment, Ceglio and Coleman (*Phys. Rev. Lett.* **39**, 20; 1977) used a similar zone-plate, coded-aperture

Lynn R. Veeser is in the Physics Division, University of California, Los Alamos.

technique to image alphaparticles from the thermonuclear burn region in an exploding pusher implosion at the Lawrence Livermore Laboratory Argus laser. They were able to detect burn regions smaller than 30 μm in targets which were initially about 90 μm in diameter, proving that the burn occurred near the target center, as was hoped, and not in the outer regions of the target.

A somewhat different approach to X-ray imaging of a laser fusion target was reported recently by Fenimore *et al.* (*Appl. Optics* **18**, 945; 1979). Their coded aperture was a plate with a large number of tiny pinholes. Since the signal-to-noise ratio is proportional to the square root of the number of holes, sensitivities comparable to that of the zone plate aperture were produced by choosing the appropriate aperture pattern. Fenimore was able to virtually eliminate undesired artifacts, such as "ghosts," in the reconstructed image. Furthermore, since digital (computer) reconstruction of the image was used, it was possible to avoid distortion of the image intensities relative to the source strength. Optical reconstruction tends to give an image for which isodensity contours correspond to isoemission contours of the source, but the image

density is not proportional to the source emission intensity. One drawback to using an aperture made with a large number of small holes is the difficulty of making each hole with an exactly known size, shape, and position to achieve the artifact-free images this method is capable of producing. Even though the 4×10^4 pinholes in the Fenimore aperture were 25-μm square, not as small as state-of-the-art fabrication techniques would permit, a very high-quality, linear image was obtained because of the care taken in the aperture construction. A camera aperture with 6-μm holes was recently built and should give increased resolution.

The technology for doing high-resolution imaging of particles and X-rays is advancing rapidly at present because of the need for improved diagnostics for laser-driven fusion implosions. The recently reported X-ray and alphaparticle imaging experiments have given valuable insight into the exploding-pusher implosion process, and we can expect further progress as high-resolution imaging becomes a routine diagnostic tool. It is quite likely that the imaging advances made because of laser-fusion needs will be of considerable use in other fields, particularly nuclear medicine. □

The present state of tranquility

from Leslie L. Iverson

MORE than 8000 tons of benzodiazepines were prescribed in 1977 in the United States. Some drugs in this group, such as diazepan (Valium) are used for their anti-anxiety properties, others such as flurazepam (Dalmane) and nitrazepam (Mogodon) as sleeping pills, and they have become the most widely used of all psychotropic drugs. It is only very recently, however, that progress has begun to be made in understanding how they work. This has been due to two important developments: the discovery of specific high affinity binding sites for radio-labelled benzodiazepines in brain (Squires & Braestrup *Nature* **266**, 732; 1977; Möhler & Okada *Science* **198**, 849; 1977), and the emergence of a plausible hypothesis to explain how benzodiazepines may interact with normal brain function. This hypothesis suggests that benzodiazepines act by enhancing the effectiveness of the important inhibitory chemical transmitter gamma-aminobutyric acid (GABA) in brain (for reviews see Iversen *Nature* **275**, 477; 1978; and Tallman *et al. Science* **207**, 276; 1980). With these two leads, biochemical research on benzodiazepine receptors in brain and their relation with GABA mechanisms has developed rapidly to become one of the most active areas of psychopharmacology.

A key question concerns the nature of the interaction between benzodiazepine and GABA receptors. The interaction is indirect, since the benzodiazepines do not simply mimic the actions of GABA, and

indeed do not compete directly with radioactive GABA for binding to GABA receptors in brain membrane preparations. Similarly GABA and related inhibitory compounds do not compete for the binding of radiolabelled benzodiazepine to their recognition sites. One possible clue about the nature of this interaction comes from a consideration of the mechanism by which GABA receptors control the excitability of brain cells. The effect of GABA when bound to its receptors is to trigger a specific change in the permeability of the cell membrane to chloride ions, and it is the movement of chloride which stabilises the electrical potential of the cell and reduces its excitability. The GABA receptor may thus be viewed as part of a macromolecular complex in which the GABA recognition site is associated with a chloride ionophore. Benzodiazepines might interact not with the GABA recognition sites but with the chloride channels to enhance the normal effects of GABA, as suggested by Guidotti *et al.* (*Nature* **275**, 553; 1978) and others. This view is also proposed by Simmonds (*Nature* **284**, 558; 1980) and supported by his new experimental findings. Simmonds studied the inhibitory effects of GABA in an *in vitro* preparation of small slices of rat cuneate nucleus using electrophysiological recording techniques. Addition of flurazepam to this preparation caused a small but significant potentiation of the effects of applied GABA. More importantly, flurazepam also significantly

weakened the ability of the GABA blocking drug picrotoxin to antogonise the effects of GABA, while it had no effect on the GABA-blocking actions of another antagonist drug, bicuculline. The significance of this finding is that whereas bicuculline is thought to act by competing directly at GABA receptors, picrotoxin acts at a different site, perhaps related to the chloride ionophore. Although flurazepam and picrotoxin do not appear to compete for the same site, the result points again to an interaction of the benzodiazepine receptor with the chloride channels associated with GABA receptors. Simmonds suggests that the benzodiazepines might increase the duration of channel opening for each GABA receptor activation, or improve the efficiency with which GABA receptor occupation is associated with channel opening.

A similar conclusion has been drawn from other lines of research on GABA/benzodiazepine mechanisms. A number of laboratories have observed that GABA increases the affinity of binding sites for radiolabelled benzodiazepines in brain membrane preparations *in vitro* (Tallman *et al. Nature* 274, 383; 1978; Briley & Langer *Eur. J. Pharmac.* 52, 129; 1978; Martin & Candy *Neuropharmac* 17, 993; 1978), and the latter authors also observed that this effect of GABA was considerably enhanced by chloride ions. Costa *et al.* (*Nature* 277, 315; 1978) tested a number of other anions and claimed that their effectiveness in causing increases in the affinity of benzodiazepine binding correlated with their ability to replace chloride in GABA-mediated inhibitory events, although this conclusion has been challenged by Martin and Candy (*Neuropharmac.* 19, 175; 1980).

An unexplained feature of the GABA effect on benzodiazepine binding is that a number of compounds which mimic the inhibitory actions of GABA on neuronal firing and which compete for ^{3}H-GABA binding sites fail to enhance benzodiazepine binding (Karobath *et al. Nature* 278, 748; 1979 and some of these compounds may even antagonise the effects of GABA on benzodiazepine binding (Braestrup *et al. Nature,* 280, 331; 1979). This suggests that the GABA recognition site which mediates changes in benzodiazepine receptor affinity may differ in specificity from that of the normal GABA inhibitory receptor.

Regardless of its pharmacological characteristics, however, the existence of a GABA recognition site which can influence the binding properties of the benzodiazepine receptor adds further support to the GABA/benzodiazepine interaction hypothesis, and an interesting recent observation is that GABA continues to exert a modifying action on the affinity of benzodiazepine binding even in solubilized

Leslie L. Iversen is Director of the MRC Neurochemical Pharmacology Unit, Department of Pharmacology, Medical School, Cambridge.

benzodiazepine receptor preparations (Gavish & Snyder *Life Sci.* 26, 579; 1979).

Our understanding of the complexity of GABA mechanisms in brain has been increased by the finding of an apparently novel type of GABA receptor which has a different drug specifity from the conventional post-synaptic inhibitory receptors for GABA. Bowery *et al.* (*Nature* 283, 92; 1980) have summarised the evidence for the existence of such a novel GABA receptor. GABA at micromolar concentrations inhibits the release of monoamine transmitters from nerve terminals in the brain and in the peripheral autonomic nervous system, but unlike conventional GABA responses these effects are not antagonised by bicuculline. The anti-spastic drug baclofen (ß-parachlorophenyl GABA) potently mimics these presynaptic effects of GABA, although this compound is inactive on post-synaptic GABA receptors.

Furthermore, the presynaptic GABA sites fail to recognise compounds such as 3-aminopropanesulphonic acid and muscimol, which are potent GABA-mimetics on post-synaptic GABA receptors. These observations suggest that a different type of GABA receptor may be involved, bringing GABA into line with other CNS neurotransmitters for which multiple receptor types are now thought to exist.

Research on the minor tranquilisers and brain GABA mechanisms is far from tranquil, although from this turmoil a better understanding is emerging of the cellular and molecular pharmacology of this major group of psychotropic drugs. At the same time rapid developments are now taking place in isolating and purifying benzodiazepine receptors and identifying possible naturally occurring ligands for them. □

Cataclysmic conferences show convergence

from Robert P. Harkness and Brian McMahon.

SINCE the discovery some sixteen years ago that novae and related variable stars were binary systems, theoreticians and observers have devoted a great deal of effort to understanding how the interactions between the two stellar components give rise to energetic outbursts on timescales ranging from weeks to thousands of years. Two recent informal conferences* on the nature and properties of cataclysmic variables have given a timely glimpse of the state of the art.

Our current understanding of dwarf novae was emphasised at Cambridge. These systems typically undergo irregularly spaced outbursts of some 2-4 magnitudes every few weeks, lasting for a few days at a time. It is believed that the energy required to power the outbursts comes from gravitational energy of matter which is transferred from the binary companion star to a white dwarf primary, and that this transferred matter forms a disc around the primary which is stable between outbursts. J. Pringle (Cambridge) presented a series of models due to him and G. T. Bath (Oxford) which follow the evolution of accretion discs following the injection of material from the companion star, demonstrating how the density and temperature distribution and the timescale of the resulting structural changes depend on the as yet poorly understood "viscosity" of the disc.

The existence of such accretion discs is rapidly being confirmed, particularly from combined ultraviolet and optical studies with the International Ultraviolet Explorer satellite (IUE) and ground-based optical telescopes. J. Whelan (Cambridge) showed the continuum spectra covering the wavelength region 1000 — 7500 Å of three dwarf novae taken simultaneously in the

optical and ultraviolet, and compared them with the spectral energy distribution predicted for a steady-state, optically thick accretion disc. For the two systems VW Hyi and EX Hya, no single stellar-type continuum could fit the data, but the fit was very reasonable for simple discs, and allowed disc effective temperatures to be deduced. The third system, BV Cen, showed a different flux distribution which was thought to yield information about the secondary star.

J. Papaloizou (Cambridge) discussed systems of the SU UMa type, which occasionally show more luminous "superoutbursts" lasting about a week. During these eruptions, the light curve contains periodic humps with a period differing slightly from the binary orbital period of the system. It is thought that these so-called "superhumps" may be due to a tidal process which excites toroidal modes of oscillation in the secondary and thus modulates the mass transfer flow with waves of the same period.

Such "superhumps" were observed by M. Friedjung (Paris) in the 1978 outburst of the recurrent nova WZ Sge. Spectroscopy with IUE indicates a continuum consistent with an accretion disc spectrum rather than the spectrum typical of a classical nova, but double-peaked emission lines which become narrower at outburst are interpreted as features representing an outer, slowly-rotating disc. Such a structure was suggested as an alternative cause of "superhumps".

At Austin, much new observational work on dwarf novae was presented, all of which was interpreted in terms of the now standard

Robert P. Harkness and Brian McMahon are in the Department of Astrophysics, University of Oxford.

accretion disc model. High-quality optical spectroscopy of the system SS Cyg was reported by E. Nather (Austin) and also by A. Cowley (Dominion Astrophysical Observatory), leading to a revised period of 0.275 days, but yielding no definite results for the mass ratio of the components. Abundances in the accretion disc were investigated by S. Wyckoff (Phoenix), who reported an excess of helium over hydrogen in the disc of EX Hya.

Satellites have produced much new data, and ultraviolet observations from IUE were reported from P. Szkody (Washington) and also by G. Fabbiano (Harvard-Smithsonian Centre for Astrophysics). F. Cordova (Los Alamos) presented recent X-ray results from the Einstein satellite for a number of systems, all of which had significant hard X-ray fluxes, while no ultrasoft emission at energies around 50 eV (as previously seen at outbursts of SS Cyg and U Gem) was detected. The failure of previous satellites to observe X-ray emission from most cataclysmic variables allows an upper limit to be put on the mean X-ray luminosity of 10^{31} ergs s^{-1}. Most of the ultraviolet and X-ray spectra presented were in reasonable accord with the general predictions of the accretion disc model.

Einstein and IUE observations of nova-like variables were presented by E. Sion (Villanova). These objects show a wider range of properties than ordinary dwarf novae. V471 Tau, in the Hyades cluster, has a primary which may be the hottest white dwarf known, with a temperature of over 60 000 K. High-excitation spectral lines of silicon and carbon seen in absorption are thought to arise in the photosphere of the white dwarf, and there is no evidence for an appreciable accretion disc. TT Ari and CD-42°4462 display similar features, but the latter in outburst has a very similar spectrum to that of the dwarf novae.

At Cambridge, an attempt to model the colours and eclipses of the nova-like variable RW Tri was made by J. Frank (Leicester) and co-workers. They assumed the presence of an accretion disc and a secondary on or near the main sequence. If their model is correct, it implies a mass for the white dwarf component of 1.4 times the mass of the sun, which is uncomfortably close to the Chandrasekhar maximum. This result was challenged in discussion by J. Smak (Warsaw), who claimed that radial velocity measurements on the system give a figure much closer to 0.4 solar masses.

The properties of systems related to the short-period binary AM Her were reviewed at Austin by J. Liebert (Tucson). These are characterised by strong linear and circular polarisation, and are usually X-ray sources. They exhibit no nova-like eruptions, but do have distinct "low" and "high" states. They are now usually interpreted as systems containing an accreting highly-magnetised white dwarf.

It is conjectured that the high magnetic fields disrupt or prevent a disc from forming, so that accretion columns are produced at the magnetic poles of the primary. Four of these systems are now known, the most recent discovery being the X-ray source 2A0311-227. Optical and X-ray light curves for this 81-minute eclipsing binary were presented by J. Patterson (Minnesota). The X-ray flux has a soft black body component, and a hard bremsstrahlung component with energies in excess of 11 keV. This latter component is not eclipsed at all, while the soft X-ray flux is halved at eclipse. This was interpreted as the eclipse of a hot spot in the accretion stream by the accretion column itself. This same object was discussed at Cambridge, where M. Watson (Leicester) explained the narrow spike appearing in one of the eclipse components of the optical light curve by the passage of the secondary star across the line of sight. The other eclipse features are then due to the eclipse of the magnetic poles by the body of the white dwarf itself.

While our knowledge of dwarf novae and related systems appears to be increasing steadily, less progress is being made on the problem of the classical novae, which undergo outbursts perhaps only every 30 000 years, but with ranges of 8-17 magnitudes. It is thought that these, too, are binary systems, but it is argued that the violence of their outbursts must be explained by thermonuclear ignition of hydrogen-rich material accreted by the white dwarf. It is generally agreed that the nova outburst produces an optically thick envelope around the whole binary system; as this envelope thins, one sees deeper into regions of higher temperature, so that the flux maximum moves into regions of shorter wavelength. Thus the bolometric (total) luminosity remains essentially

constant for some time, while the visual luminosity drops off rapidly. If this picture is right, one would expect to see enhanced abundances of such elements as carbon and nitrogen which are necessary to fuel the thermonuclear runaway. At Cambridge, C. Penn (London) discussed ultraviolet observations of Nova Cyg 1978 following outburst, the first time a classical nova eruption has been seen by IUE. The development of several spectral lines was followed for nearly a year, and in the early stages of the outburst many showed the P Cygni profiles expected for outflowing material. Measurements were made of carbon and nitrogen which showed them to be highly overabundant in the nebular phase.

The Austin meeting heard from M. Shara (Montreal) a theoretical paper seeking to derive the empirical relation which has long been established between the maximum magnitude of a classical nova and the speed with which it subsequently drops in luminosity by three magnitudes. This relation is of wider importance in astronomy, since a good theoretical basis for the empirically observed result would allow classical novae to be used as "standard candles" and distance indicators with greater confidence.

The Austin meeting was the fifth in an irregular series of workshops on cataclysmic variables, the Cambridge meeting the first such to be held in Britain. The range of activity demonstrated the excitement and dynamism of the subject. Now that interpretations seem to be hardening on specific theoretical models, a flurry of more detailed calculations can be anticipated, including as a major contribution models of accretion disc structure that can be compared with a large array of observational tests. □

Structural aspects of recognition and assembly in biological macromolecules

from a Correspondent

THE last decade has witnessed a dramatic increase in our understanding of the structural, thermodynamic and kinetic factors which allow recognition and assembly in molecular biology. More complex supramolecular systems have been subjected to the techniques of amino acid and nucleic acid sequencing, to high resolution X-ray analysis and spectroscopic probes, and to mechanistic and functional investigations. We can now begin to asses the role of shape, hydrophobicity, flexibility and other factors in the processes of recognition between biological molecules. This was the theme of the VIIth Aharon Katzir-

Katchalsky Conference held at Kibbutz Nof Ginossar on the shore of the Sea of Galilee, Israel, earlier this year.

Of the many biomolecular systems, enzyme substrate interactions have been most thoroughly investigated; but only recently have very high resolution (~ 1.5A) X-ray studies allowed precise definition of the molecular geometry and thermal vibrations — a measure of at least one kind of flexibility. This is proving a critical testing ground for older hypotheses of catalytic mechanism involving steric strain, charge relay systems and covalent intermediates. For instance, M.N. James and his colleagues (University of Alberta) have

cast doubt on the accepted mechanism of serine proteinases by their detailed analyses of the serine proteinase A from *Streptomyces griseus* where they find bond distances which are considerably longer than expected in the charge relay system, tetrahedral intermediate model now described in all our biochemistry text books. They also demonstrate the existence of highly ordered water in the active site which must be displaced by the solvent; the release of this water would be entropically favourable to the assembly of the complex. Another striking feature of this work is the observation that although there is high thermal motion of the "jaws" of the substrate-binding site in the native enzyme, the polypeptide in this region becomes significantly more rigid in the presence of a ligand. The flexibility may play an important role in the docking of substrate with the enzyme. Similar ordering is found by R. Huber's group (Max-Planck-Institute, Munich) in a disordered "activation domain" in trypsinogen which includes part of the specificity site when the bovine pancreatic trypsin inhibitor or other inhibitors are bound in the presence of an activator dipeptide. K. Wüthrich (ETH, Zürich) reported similar order-disorder transitions in solution using nuclear magnetic resonance studies, and it is now becoming clear that such transitions may be of general functional importance in interactions between different biological systems.

Progress is also being made in our understanding of the assembly of fibrous proteins, especially in muscle components. For instance, the amino acid sequence of tropomyosin shows a number of periodic and non-periodic features which can be correlated with its two-stranded coiled-coil structure, with its head-to-tail aggregation into long filaments, and with its interactions with F-actin and troponin (L.B. Smillie, University of Alberta). A mechanism was described whereby tropomyosin regulates muscular contraction by responding to structural changes induced in troponin in Ca^{++} ions and consequently rolling across the surface of actin, thereby uncovering the site for actin binding to myosin (D.A.D. Parry, Massey University). New results concerning the binding of myosin cross-bridges to actin suggest that these may not change their slope during contraction (K. Holmes, Max-Planck-Institute, Heidelberg) and that the contractile force may result from a helix-coil transition in the S_2 fragment of myosin (W.F. Harrington, Johns Hopkins).

Although models for the recognition of DNA by proteins have until recently assumed a dimorphic DNA consisting of only the B and A forms, it is now clear that the DNA molecule is much less rigid than previously believed. S. Arnott (Purdue University) presented evidence from fibre X-ray diffraction studies for a great variety of possible DNA double helical structures.

These structures are mostly right-handed, but specific polymers of alternating purine and pyrimidine bases were found to form left-handed duplexes similar to the Z DNA structure (*Nature* **282**, 680; 1979). Although it is generally believed that most DNA has a classical DNA double helix most of the time it is probable that such specific structures in parts of DNA may be involved in their recognition by binding proteins. H. Sobell (University of Rochester) suggested that thermally induced low-frequency-mode oscillations in a DNA duplex structure may play a central role in transitions between different structures and in the binding of other molecules to DNA.

The exact pitch of DNA in a natural environment may also differ from that in the fibres which formed the basis of the Watson-Crick double helix. A. Klug (MRC, Cambridge) described some recent experiments aimed at measuring the true pitch of DNA in solution by cleaving molecules on a very flat mica surface with DNase I. The pitch was found to be 10.6 bases; significantly different from the 10.0 bases measured in X-ray fibre studies, but quite similar to the average value of 10.4 suggested from DNase I digestion of chromatin DNA. E. Trifonov (Weizmann Institute) described a quite surprising result that the distributions of the dinucleotides CG, TG, TA and TT along DNA sequences found in chromatin are periodic. The period is about 10.5 bases which agrees within error limits with previous estimates of the pitch of DNA in chromatin.

Evidence for small variations in t-RNA structures which may be important in their recognition is also forthcoming from the structure analyses of yeast initiator t-RNA$^{Met}_f$ by J. Sussman (Weizmann Institute; see *Nature* **278**, 188; 1979) and yeast t-RNA^{Asp} by J-C. Thierry (University Louis Pasteur, Strasbourg). In contrast to the class I, chain elongation t-RNA^{Phe}, the t-RNA$^{Met}_f$ is a chain initiation t-RNA and the t-RNA^{Asp} is a class II t-RNA. Both show the canonical "L" shaped conformation of t-RNA^{Phe} but there are differences in the closing of the angle between the two long helical stems of the "L" by about 8° in t-RNA$^{Met}_f$ and the opening of this angle by about 10° in t-RNA^{Asp}. P. Sigler (Chicago University) proposed an intriguing hypothesis for the molecular basis of the unique role played by eukaryotic initiator t-RNAs in protein synthesis, suggested to him by the t-RNA$^{Met}_f$ crystal structure. The characteristic sequence features which are common and unique to eukaryotic initiator t-RNAs are clustered in a 10Å domain at the union of the D and T loops and fold in a way that preserved the backbone trace seen in other t-RNAs. However, the potential for unique interactions with cognate proteins and nucleic acids makes this region a likely focus for the specific interactions with the ribosome, that underlie the special role of t-RNA$^{Met}_f$. These

interactions stabilise a factor-mediated 80s ribosomal initiation complex which recognises the first AUG encountered from the 5'-terminus of the m-RNA as the "Start" signal.

The recently determined structure of the Southern Bean Mosaic Virus, SBMV (M. Rossmann, Purdue University) shows that there may be common features in the assembly of spherical viruses. A comparison of its structure with that of Tomato Bushy Stunt Virus, TBSV (S. Harrison, Harvard University) indicates a conformation similar to that of the shell domain of the latter. The SBMV protein also uses a similar pattern of contacts with neighbouring molecules within the viral capsid. Studying the inter-subunit contacts in the shell domain of TBSV, Harrison has found an alternating pattern of polar and hydrophobic patches, as previously found for the lateral interactions in Tobacco Mosaic Virus (A. Bloomer *et al*, MRC, Cambridge), and he suggested that this may be a general feature of interfaces which can exist in more than one quasi-equivalent state. The three types of interaction between hexons in the capsid of adenovirus (R.M. Burnett, Biocentrum, Basel) can now be understood in terms of the pseudo-hexagonal symmetry of the trimeric protein. The symmetry facilitates packing, whereas the departures from it allow the different interactions.

It is hoped that the proper understanding of recognition in self-assembling systems may provide the basis for a contribution of molecular biology to medicine. X-ray studies of fibres and crystals of deoxygenated sickle-cell haemoglobin have led to a model for the interactions specific to the mutant haemoglobin. M. Gorecki (Weizmann Institute) described the design of small peptides and esters of hydrophobic amino acids based on this model. These compounds appear to inhibit sickle cell haemoglobin aggregation, they permeate erythrocytes rapidly, and thus appear to have considerable potential for the therapeutic treatment of sickle cell anaemia. In a similar way analyses of three-dimensional models for insulin and glucagon receptor interactions (T.L. Blundell, Birckbeck College, London) have led to pharmaceutical activity in the design of insulin agonists and glucagon antagonists which may be of value in the treatment of diabetes. The recent determination of the first three-dimensional structure of a long neurotoxin by M. Walkinshaw and W. Saenger (Max-Planck-Institute, Göttingen) has suggested a refined model for the multipoint attachment of toxins to the nicotinic acetylcholine receptors which must stimulate the design of new neuromuscular blocking agents. Even greater rewards may come from studying some of the more complex structures. For instance, it will be surprising if our new knowledge of virus coat structures does not lead to the design of some useful antiviral agents. □

Northward displacement of north-central British Columbia

J. W. H. Monger

Geological Survey of Canada, 100 West Pender Street, Vancouver, Canada V6B 1R8

E. Irving

Earth Physics Branch, Energy, Mines and Resources, Ottawa, Canada K1A OE4

An extensive terrain in north-central British Columbia, apparently moved ~1,300 km northwards along the western fringe of North America during the late Cretaceous or early Tertiary, perhaps in much the same fashion as Baja California is doing today. Large anticlockwise rotations occurred within this terrain.

THE western, volcanosedimentary 'eugeosyncline' of the North American Cordillera is a collage of terrains of varied origins that apparently became attached to the western continental margin of the continent at different times[1-3]. These terrains now lie to the west of the line WW in Fig. 1, which is the probable western limit of the ancient North American craton. It is delineated by the westernmost limit of Palaeozoic and Precambrian strata whose continuity with the craton can be reasonably inferred, and by the transition of the $^{87}Sr/^{86}Sr$ initial ratios from <0.704 to the west (indicating that the underlying crust is of oceanic or island arc origin) to >0.706 to the east (indicative of continental crust)[4]. EE is the eastern limit of Cordilleran deformation.

The concept of a tectonic collage derives from several lines of evidence. Each terrain has an early Mesozoic and late Palaeozoic stratigraphy which differs from that of contiguous terrains[5,6], each has early Mesozoic and late Palaeozoic faunas that differ from coeval faunas along the ancient cratonic margin[7,8], and several have yielded palaeomagnetic results indicating that they have been displaced latitudinally or rotated by large angles about local vertical axes[9-12]. The Alaskan peninsula and the Chugach Mountains (SAJ of Fig. 1), composed of Jurassic and younger rocks, have been displaced 1,500 km from the south since the Jurassic[10]. A western terrain[13], sometimes called Wrangellia[5], with distinctive Triassic stratigraphy, comprises parts of southeastern Alaska, Queen Charlotte Islands, Vancouver Island and the Hell's Canyon area of eastern Oregon the latter denoted by '?' in Fig. 1b. Wrangellia has moved at least 1,500 km, and possibly as much as 5,000 km, from the south since the late Triassic[9,11]. Much of southeastern Alaska is underlain by the Alexander terrain, with characteristic Palaeozoic and Triassic strata[14]. Recent palaeomagnetic results[15] from the Alexander terrain indicate large anticlockwise rotations and yield Triassic palaeolatitudes consistent with those for the craton. Instances of northward displacements and clockwise rotations have been reported from batholithic rocks[16,17]. The Coast Range of Oregon[18,19], and the Transverse Ranges of southern California[20] have rotated clockwise by ~60° during the Tertiary. We now present palaeomagnetic evidence from a reconnaissance survey for the northwards displacement and differential rotation of an extensive tract of country in northern British Columbia known as the Stikine terrain, together with rocks of the Cache Creek Group that lie along its eastern border.

The integrity of the Stikine terrain during the early Mesozoic is shown by the distinctive late Triassic and early to middle Jurassic rocks that extend across it. It is bordered to the east by the Cache Creek Group, which lies just west of WW. The Cache Creek Group is interpreted as late Palaeozoic–early Mesozoic ancestral Pacific Ocean crust with its overlying deposits that were thrust westwards on to the Stikine terrain in post-Oxfordian time[2,6,21]. To the east of WW there are volcanogenic terrains that may have formed along or immediately offshore from the Pacific margin of North America during the Mesozoic[2]. The displacement of terrains in the western Cordillera from the south has been suggested first to account for the juxtaposition of warmer-water western Triassic faunas and cooler-water faunas in the Rocky Mountains[7], and second to explain the peculiar distribution of Permian fusulinids whereby the Cache Creek Group, with its distinctive verbeekinid or Tethyan faunas, was inserted between schwagerinid or American faunas that occur to the west in the Stikine terrain and to the east and south in south-central British Columbia, Oregon and California[8]. Our palaeomagnetic studies were undertaken to make quantitative estimates of any displacements that might have occurred.

Palaeomagnetic results

The rocks sampled are Upper Triassic and Lower Jurassic volcanogenic strata, typical of the Stikine terrain, and a Lower Cretaceous layered intrusion cutting deformed Cache Creek rocks (Fig. 2). These three rock units were sampled at 42 sites distributed among six localities. Within each locality the sequences are continuous, with no field evidence of relative motion. Attitudes of bedding, flow layering or compositional layering were measured at each site, with the exception of some massive augite porphyries at the base of the Triassic section (Table 1, section (7)), but their continuity with overlying, compositionally similar, uniformly dipping flows suggests they have the same attitudes. Three to six oriented samples (cores or hand samples) were obtained from each site. Two cores were cut from each hand sample, making a total of 236 cores. Two specimens were cut and measured from each core.

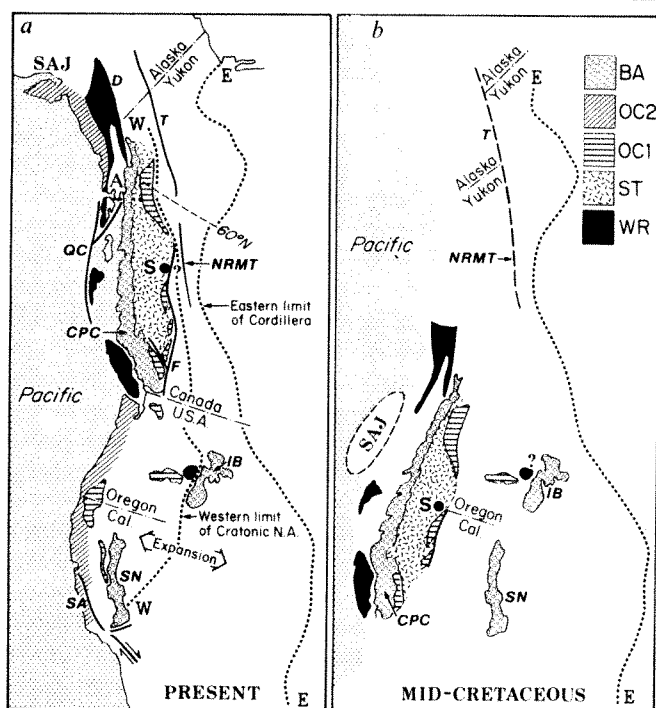
The oldest rocks studied are from the Savage Mountain Formation of the Takla Group of late Carnian to earliest Norian age[22]. The Savage Mountain Formation consists of up to 5,000 m of dark grey-green, locally red, pillow basalt and massive subaerial flows, with associated volcanoclastics. Samples were obtained from two localities, mainly from subaerial flows. At all collecting sites, with the exception noted above, attitudes could be accurately measured. When sampling


Fig. 1 *a*, A sketch-map showing some of the major tectonic elements of the Cordillera. EE is the easterly limit of deformation; WW, the westerly limit of the North American craton. BA, major plutons (CPC, Coast Plutonic Complex; IB, Idaho batholith; SN, Sierra Nevada batholith); WR, Wrangellia; ST, Stikine terrain; OC1, mid-Jurassic and older oceanic crust and rocks deposited on it; OC2, late Mesozoic and Tertiary oceanic crust and rocks deposited on it; A, the Alexander terrain is the blank area. *b*, The proposed position of the Stikine and Wrangellian terrains during the late Triassic to mid-Cretaceous. The Tertiary expansion of the Basin and Range Province is restored, and Wrangellia and the Coast Plutonic Complex are attached to the Stikine terrain in their present relative positions. These terrains are moved undistorted. We consider only gross latitudinal displacement, and no attempt is made to restore the original geometries of individual elements of the Stikine and Wrangellian terrains. Certainly large internal rotations are involved (see text). Major right-lateral strike-slip faults are marked: *D*, Denali; *F*, Frazer; *NRMT*, Northern Rocky Mountain Trench; *QC*, Queen Charlotte Island–Chatham Strait system; *SA*, San Andreas; *T*, Tintina. S is the sampling area, and SAJ is the late Jurassic displaced terrain of southern Alaska[10]. In *b* the Alaska–Yukon border is displaced on the Tintina–Northern Rocky Mountain Trench lineament to show the amount of motion that can be demonstrated geologically on one of the fault systems that might record some of the northward displacement of the Stikine terrain. The total displacement occurred by motions of comparable magnitude distributed among several such faults (see text).

Takla and Hazelton rocks, preference was given to deuterically oxidized basalts, because such rock types have been shown to be very stable magnetically[23], and our preliminary studies confirmed that this was also true for the sequences we have sampled (Fig. 3). Such oxidized rocks can usually be recognized by diagnostic minerals such as iddingsite in olivine basalts, because they are often reddish, and because they yield grey-red mud when drilled. The Takla basalts have alkaline affinities, and are generally porphyritic, with abundant clinopyroxene, feldspar, and altered olivine phenocrysts. The directions of natural remanent magnetizations (NRM) at each site are sometimes scattered, but are more commonly well grouped. During cleaning by alternating field (30–80 mT) or thermally (550–600 °C), they coalesce into good groups. The same directions persist after treatment in fields of 150 mT, and in some specimens, up to 200 mT. Blocking temperatures of this high coercive force magnetization are in the range 500–650 °C, and haematite and magnetite blocking temperatures often occur in the same specimen (Fig. 3). The directions remain unchanged between 500 and 650 °C, the haematite and magnetite magnetizations having identical directions. After cleaning, and after correction is made for the dip of the beds, the directions are westerly. This direction characterizes the

Savage Mountain Formation in the places sampled. The two localities have statistically identical inclinations, but their mean declinations differ by 19° as if they have been rotated relative to one another about vertical axes (Fig. 4, Table 1). The mean inclination of 41° yields a palaeolatitude of 23°, which is significantly lower than the late Triassic palaeolatitudes calculated from cratonic North America (Fig. 5).

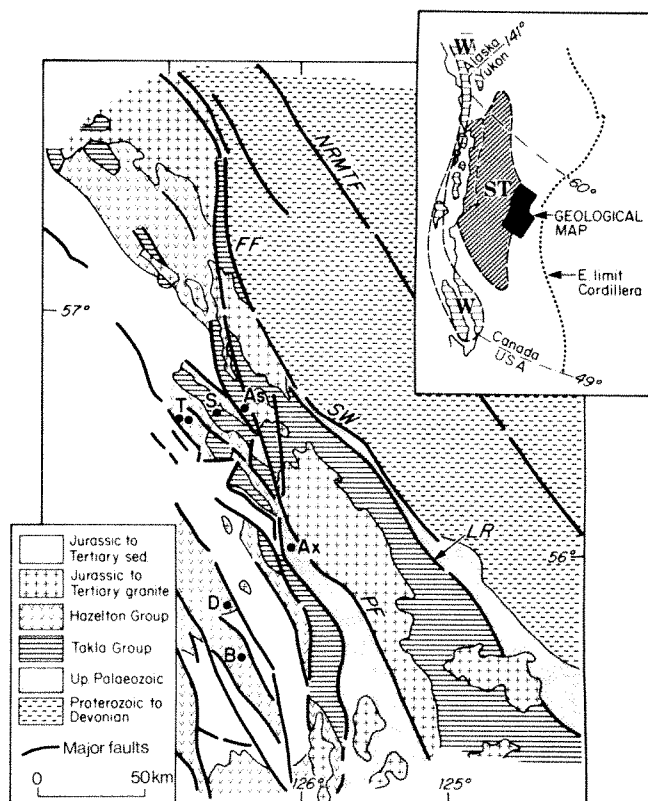
Lower Jurassic rocks of the Hazelton Group were sampled at three localities spread over 100 km (Fig. 2). The Hazelton Group consist of calc-alkaline volcanics and intercalated sediments. It ranges in age from late Sinemurian to early Callovian, and extends across the eastern and southern parts of the Stikine terrain[24]. The group contains three formations: Telkwa (bottom), Nilkitkwa and Smithers (top). Late Sinemurian subaerial red basalt, and red fine-grained tuff of the Telkwa Formation were sampled from the Red Creek–Two Lake Creek area, and the Driftwood Range. Toarcian basalt and red tuff of the Nilkitkwa Formation were obtained from the Bait Range. The directions of NRM at each collecting site are usually grouped together but are occasionally scattered. Cleaning by alternating fields and heating yields well-grouped directions. The coercivity commonly exceeds 100 mT, and blocking temperatures are in the range of 500 to 700 °C, except in some tuffs in which the range is 200–600 °C (Fig. 3). The directions at the sites within a locality agree reasonably well. Moreover, the mean inclinations are statistically identical from locality to locality, but the declinations range from south-west to north-east (Fig. 4, Table 1), as if the localities have been differentially rotated by large angles about vertical axes. Alternatively, one may argue that these directions (unrotated) could be the resultants of unresolved antiparallel magnetization acquired over a substantial time interval during lithification when the geomagnetic field reversed in direction. This is improbable


Fig. 2 Geology of the sampling region. The sampling localities are: As, Asitka Peak; Ax, Axelgold intrusion; B, Bait Range; S, Sustut Peak; and T, Two Lake Creek and Red Creek localities. The inset shows the general location and the two major displaced terrains, Wrangellia, W, and the Stikine terrain, ST. The faults marked are: FF, Findlay; LR, Lay Range; NRMT, Northern Rocky Mountain Trench; PF, Pinchi; and SW, Swannell.

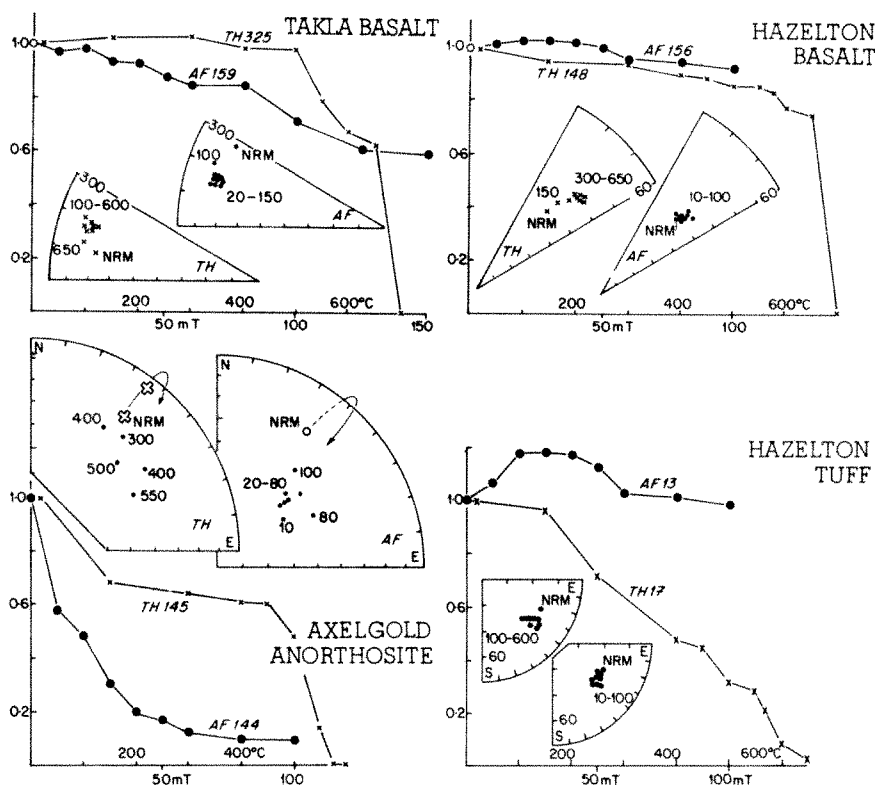
Fig. 3 Demagnetization studies. Examples of thermal (TH) and alternating field (AF) demagnetization of pairs of specimens from the same oriented core. Directions are plotted on equal-area projections, the plane is the present horizontal. The numbers on the demagnetization graphs are the intensities of natural remanent magnetization (NRM) in units of 10^{-3} A m^{-1}. The Takla and Hazelton basalts are deuterically oxidized; the directions are little changed throughout the demagnetization range; remanent coercive forces are high; blocking temperatures appropriate to haematite and fine-grained magnetite occur; both minerals can be identified in polished section and both have the same magnetization direction; inclinations are positive (downward). In the Axelgold anorthosite the directions initially have negative inclination and they migrate rapidly to the characteristic direction (inclination positive) for the intrusion during removal of a soft magnetization which is randomly directed from core to core and which we attribute to lightning; there is a well-marked 'magnetite' blocking temperature; in polished section magnetite occurs as very fine rods in felspar crystals; remanent coercive forces are typical of those of fine-grained magnetite; haematite magnetizations do not occur. The red tuff from the Hazelton Group has negative inclination and the direction is little changed through the demagnetization range; the magnetization is due to very fine-grained hematite readily observed in polished section.


because the haematite and magnetite magnetizations that probably formed at somewhat different times always have identical directions (Fig. 3). Moreover, it is highly improbable that such a complex magnetic structure would have produced inclinations of both normal and reversed magnetizations that are consistent from locality to locality. A further possibility is that the directions (unrotated) are the resultants of primary magnetizations and stable secondary magnetizations, the latter acquired long after formation. Again, such an interpretation is highly improbable for the two reasons just given, and because we have been careful never to sample close to later igneous bodies or zones of secondary mineralization. Therefore we conclude that large relative rotations have occurred. A mean inclination (54°) is obtained by rotating all site directions so that the mean declinations at each locality agree (Hazelton rotated, Fig. 4). The mean palaeolatitude of 35° is 14° farther south than expected, but the difference is marginally significant. The large error of Fig. 5 arises from the considerable uncertainty in the early Jurassic field direction for cratonic North America as it is presently known (see below). These results from the Hazelton Group provide one of the few well-documented instances of reversals of magnetization in early Jurassic rocks.

The third unit is the Axelgold Intrusion, a layered body, 12 by 4.5 km in extent[25]. Its age is less well defined than in the previous two units. The body intrudes highly deformed rocks of the Cache Creek Group, and cuts structures that, 25 km to the north, are congruent with structures of post-Oxfordian age. The intrusion is therefore post-Oxfordian. Two biotites and one hornblende from the reaction rim of a granite xenolith in the interior of the intrusion, and from a micaceous gabbro close to the contract, yield K–Ar ages in the range 98–108 Myr (ref. 25). A second hornblende gives a K–Ar age of 155 Myr, but is considered[25] to "reflect the presence of excess argon". A mid-Cretaceous age is the most probable[25], but an early Cretaceous or late Jurassic age cannot be discounted. A mid-Cretaceous age is also consistent with the fact that we have found only normal polarities in the body, and normal polarity typifies the geomagnetic field in the interval 82–110 Myr (ref. 26). If it were late Jurassic or early Cretaceous, both normal and reversed polarity would have been expected in such a

large slowly-cooled body, because field reversals were then frequent[26].

The intrusion comprises alternating layers of anorthosite and anorthositic gabbro, ranging from ~10 to 50 cm in thickness, and dipping 10–15°. Anorthositic samples were chosen preferentially because preliminary studies showed them to be more stable magnetically. The layering was presumably produced by gravity-controlled magnetic currents and is therefore considered to be a good indicator of the palaeohorizontal. The NRM directions are usually scattered, but after cleaning in alternating magnetic fields they become well grouped, the characteristic magnetization having north-northeast declinations and steep downward inclinations (Fig. 4). The coercivity commonly exceeds 50 mT and the blocking temperatures are in the range of 500 to 600 °C. The mean inclination relative to layering is 69°, yielding a palaeolatitude of 52°, about 13° lower than expected for the mid-Cretaceous. It is possible that the layering was not formed horizontally, or that tilting occurred before the acquisition of remanence whilst the body was hot, and this estimate of palaeolatitude would then be in error. Note that the directions of magnetization relative to present horizontal (Table 1) yield a palaeolatitude of 40° which is even more aberrant. A further source of error is in the age of the intrusion. If it were late Jurassic, then the estimate of palaeolatitude would be in good agreement with that expected for North America at that time (see ref. 12, Fig. 15), implying that both the Cache Creek terrain, into which the body is intruded and the Stikine terrain were then in place relative to cratonic North America. Thus it is important to note that our preferred interpretation of Fig. 5 is uncertain because of the difficulty in determining accurately the age and the palaeohorizontal.

Discussion

The results for these three time intervals all yield mean palaeolatitudes that are close to the latitude of the California-Oregon boundary. The Stikine terrain is geologically a coherent entity so that although the observations are from a geographically restricted area they, nevertheless, indicate that from the late Triassic until sometime in the Jurassic or

Table 1 Summary of results

	Th	B	n	D, I	k	$\alpha_{95}°$	Pole λ, ϕ	$(dm°, dp°)$
(1) Axelgold, 98–108 Myr	270	13	67	025°, +69°	70	05	76°N, 033°W	(08, 07)
(2) Axelgold, uncorrected	270	13	67	032°, +60°	92	04	64°N, 012°W	(07, 05)
(3) Hazelton, mid-Toarcian	170	07	37	359°, +55°	15	16	70°N, 057°E	(22, 16)
(4) Hazelton, Sinemurian	070	04	28	242°, +56°	29	18	17°N, 175°W	(25, 18)
(5) Hazelton, Sinemurian	125	04	20	114°, −52°	14	25	40°N, 144°E	(35, 24)
(6) Takla, late Triassic	150	06	42	300°, +44°	31	06	38°N, 133°E	(15, 10)
(7) Takla, late Triassic	200	08	42	281°, +38°	18	07	24°N, 146°E	(16, 09)

(1) Axelgold layered intrusion, Axelgold Range 56.2°N, 126.1°W, cleaning 30–60 mT, normal polarity, direction relative to layering. Axelgold, directions relative to present horizontal. The precisions of (1) and (2) do not differ significantly. (3) Nilkitkwa Formation, Hazelton Group, Bait Range 55.6°N, 126.4°W, cleaning 550–600 °C, two sites reversed five sites normal polarity. (4) Telkwa Formation, Hazelton Group, Driftwood Range 55.8°N, 126.6°W, cleaning 80 mT and 550 °C, all normal polarity. (5) Telkwa Formation, Hazelton Group, Red Creek–Two Lake Creek area 56.5°N, 126.8°W, cleaning 550–600 °C and 60 mT, all reversed. (6) Savage Mountain Formation, Asitka Peak 56.7°N, 126.4°W, cleaning 60 mT and 500–550 °C, all normal polarity. (7) Savage Mountain Formation, Sustut Peak 56.6°N, 126.5°W, cleaning 60 mT and 500–550 °C, all normal. Directions in (3) to (7) are relative to bedding. Th, thickness of the section sampled in metres; B, number of sites each given unit weight in the analysis; n, number of cores (two specimens per core studied); D, I the mean direction; k, Fisher's estimate of precision; α_{95}, the 95% circle of confidence[35]. The position of the north pole is given; λ latitude, ϕ longitude. Unit weight given to each sampling site in the analysis.

Cretaceous the Stikine terrain was located ~1,300 km south of its present position relative to North America (Fig. 1).

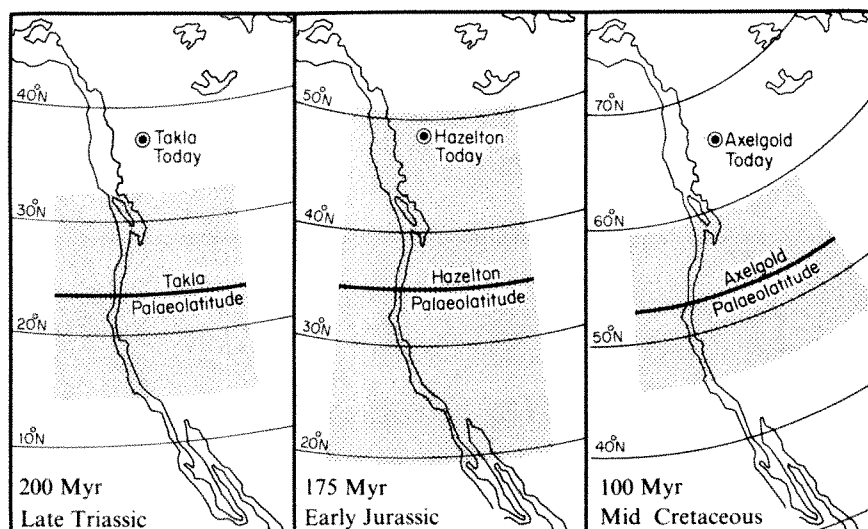
The agreement between the mean values is excellent, better than would be expected from the associated errors (Fig. 5). The errors in palaeolatitudes of the base-maps have been obtained by giving unit weight to each rock unit when calculating the statistics of the mean polar wander path for North America[12] rather than to each determination of the geomagnetic field, that is, to each sampling site, of which there

Fig. 4 Mean directions of characteristic magnetization at each collecting site. Directions are plotted on the lower hemisphere and the perimeter is the palaeohorizontal. The magnetization have normal polarity (north-seeking directions plotted) in the Axelgold and Takla rocks. In the Hazelton both polarities occur and the reversed directions (south-seeking directions, S) are shown by open symbols. In d Hazelton results are shown unrotated, correction being made for geological dip only. In c the directions are 'corrected' for rotations about local vertical axes (see text).

may be many in an individual study. The combined error estimates of Fig. 5 may therefore be too large. To use a procedure (that of giving unit weight to each rock unit) that probably overestimates errors seems more prudent than to use a method (that of giving sites unit weight) that probably underestimates them.

We suggest that the most probable time of motion of the Stikine terrain from its more southerly position was latest Cretaceous or early Tertiary. The apparent absence of post-Triassic palaeolatitudinal motion of the Alexander terrain relative to the craton[15] indicates that the Stikine block became wedged in behind the Alexander terrain at that time. The older limit for the time of this motion is set by the Axelgold intrusion whose age uncertainty has already been discussed. An important additional argument in favour of this late motion comes from considering the palaeomagnetic evidence from the Coast Plutonic Complex (CPC of Fig. 1). The Coast Plutonic Complex is a belt of Cretaceous and early Tertiary intrusions and metamorphic bodies that has not been disrupted by later deformation. The Stikine terrain is attached to the complex because it is intruded by them. Magnetic inclinations observed in Cretaceous intrusions within the Coast Plutonic Complex (such as the Howe Sound pluton[27]) are systematically too shallow, indicating that they were emplaced 10° or more south of their present position (see ref. 17, Fig. 3). Such data suffer from the absence of accurate corrections for possible post-emplacement tilt, but the effect is systematic over 400 km, and indicate a latest Cretaceous or earlier displacement consistent with our results.

A displacement of this magnitude, so late in the history of the Cordillera, and occurring so far to the east, raises the question of where the differential movement with stable North America is located. There is no geological evidence of such a late ocean closure between the localities sampled and the craton. The Cache Creek Group is thought to be ancestral Pacific Ocean floor which was thrust westward over the eastern margin of the Stikine terrain in post-Oxfordian time. Three major faults lie east of the localities sampled, and on two of them dextral strike-slip movement has been reported. The Pinchi Fault (Fig. 2) may have been a transform fault in the late Triassic, and right-lateral slip has probably recurred along it in the late Cretaceous and/or early Tertiary[28,29]. The Swannell Fault, situated to the east of the Pinchi, juxtaposes metamorphosed Proterozoic strata against later Palaeozoic and early Mesozoic volcanogenic rocks, and may mark the ancient cratonic margin at this point. No evidence of lateral slip has been reported from it. The northern Rocky Mountain Trench is the site of the third major fault (Fig. 2). Almost certainly right-lateral slip has occurred on it, but the amount

Fig. 5 Palaeolatitudes of the Stikine terrain compared with those calculated from cratonic North America. The reference palaeopoles[12] used for North America are for 200 Myr 68°N, 093°E, for 175 Myr 78°N, 110°E, for 100 Myr 69°N, 188E. The error zones $(P=0.05)$ combine the errors in both base maps and palaeolatitude observations from the Stikine terrain. Error estimates are probably too large (see text).


is unknown. It probably extends northwards into the Yukon Territory as the Tintina Fault (Fig. 1). Between 350 and 500 km of right-lateral movements since the mid-Cretaceous has been reported from the Tintina Fault[30,31], and the displacement may, in part, continue down the northern Rocky Mountain Trench and, in part, diverge westwards down such faults as the Pinchi and the Frazer lineaments (F, Fig. 1). The motions that can be documented geologically are much less than the 1,300 km derived from our evidence. For reasons discussed elsewhere[32] Wrangellia was very probably attached to the Stikine terrain (Fig. 1) and rode northwards with it in the late Mesozoic or early Tertiary[32].

Our interpretation conflicts with that of Symons[33] who argues that the area "has not been tectonically rotated or translated relative to stable North America". His arguments are based on his palaeomagnetic results from the Topley intrusions of the Stikine terrain. These intrusions are Jurassic in age, probably somewhat younger than the Hazelton Group. The Topley region has been intruded and partially covered by early Tertiary igneous rocks which have yielded K–Ar ages of between 50 and 63 Myr, and there was extensive hydrothermal activity and mineralization of economic importance at this time. We believe that Symons has misinterpreted his data, which are in fact consistent with our own. Symons' results (ref. 33, Fig. 3 and Table 1) fall into two distinct groups (A and B) which we believe have two separate origins. A magnetizations occur at eight sites in four of the Topley intrusions. They have a high mean stability index $(SI = 20)$ (ref. 33), normal and reversed polarity, and a mean inclination of 47°, corresponding to a palaeolatitude of 30° indistinguishable from that we find for the Hazelton (Fig. 5). The declinations are scattered and range from 294 to 348°, indicating variable anticlockwise rotations among the four Topley intrusions similar to the rotations we find for the Hazelton. The A magnetizations are, therefore, very similar to the magnetization of the Hazelton Group, and we suggest that they are primary and represent the Jurassic geomagnetic field. B magnetizations occur at seven sites in three other Topley intrusions[33]. Their polarity is always normal, they have a low mean stability index $(SI = 4)$, and are well grouped with much steeper inclinations than A $(D = 336°, I = 74°; N = 7; k = 96; \alpha_{95} = 6°)$. The corresponding pole, 75°N, 176°W, is statistically identical with the mean pole for North America at 60 Myr (77°N, 173°W; $\alpha_{95} = 7°$) (ref. 12). Hence, the less stable B magnetization was apparently acquired during the early Tertiary when igneous and hydrothermal activity was widespread in the Topley area. Symons averages all his results together and obtains a mean inclination of 63°, corresponding to a palaeolatitude of 40° $\pm 11°$, which is not significantly different from that expected

from cratonic North America. We suggest that his average result has no tectonic significance because it is derived from combining a Jurassic magnetization (A) with a Tertiary magnetization (B).

Although the continuity of rock units indicates that the Stikine terrain has behaved as a coherent entity, it has not behaved as a rigid plate, because the declinations of the magnetizations directions are highly variable (Table 1). On its eastern margin the Axelgold Intrusion has rotated 63° clockwise relative to cratonic North America (rotations were calculated using equation (9.2) ref. 18). Clockwise rotations are very common in the western Cordillera, and have been ascribed to motions of small blocks activated by right-lateral shear of the Pacific and North American plates—the so-called 'ball-bearing' hypothesis[34]. However, our palaeomagnetic declinations show large, variable and commonly anticlockwise rotations; 43° and 62° for the two Takla localities, 41° and 103° for two of the Hazelton localities and 14° clockwise for the third. Of course, the observed western declinations could be caused by much larger clockwise rotation (360° less the above angles) and so bring their sense of rotation into line with those generally found in the western Cordillera. However, the simplest explanation is that different parts of the Stikine terrain have undergone variable amounts of predominantly anticlockwise rotation relative to cratonic North America. This is inconsistent with the simple ball-bearing hypothesis[34]. The Stikine terrain at least in its eastern part seems to be an assemblage of slices of crust of continental thickness with areal dimensions comparable to or less than the thickness of the lithosphere, and which are separated by faults with high strains (Fig. 2). Within each slice the strata are only gently tilted or folded[24].

Different species of messenger RNA encode receptor and secretory IgM μ chains differing at their carboxy termini

Paul A. Singer*, Helen H. Singer* & Alan R. Williamson

Department of Biochemistry, University of Glasgow, Glasgow, G12 8QQ, UK

Biosynthetic studies in the presence of an inhibitor of glycosylation indicate that individual human lymphoma-derived cell lines can synthesize both membrane receptor and presumptive secretory forms of IgM μ chains. The receptor form has a larger polypeptide chain than the secretory form and possesses a different C-terminus, but similar N-terminus, consistent with the presence of a C-terminal hydrophobic 'tail' for integral membrane binding. Messenger RNA isolated from these cells directs the synthesis of both forms of μ chain in a wheat germ translation system, indicating the presence of independent mRNAs for each form. It is proposed that the synthetic pathways for receptor and secretory IgM diverge at the post-transcriptional level, possibly by differential RNA splicing to give mRNA molecules with or without a translatable 'tail' segment.

RECEPTOR immunoglobulin molecules on the surface of B lymphocytes behave in many respects like typical integral membrane proteins. By contrast, serum immunoglobulins, which function as effector antibodies, are hydrophilic globular proteins. It is reasonable to postulate that this dichotomy of function of immunoglobulins is dictated by a duality of structure. For instance, the immunoglobulin heavy chain may be expected to possess restricted regions of hydrophobicity which would function in membrane interaction. However, serum immunoglobulins do not seem to possess such hydrophobic regions. This observation has led previous workers to postulate the presence of a hydrophobic peptide on the receptor form of immunoglobulin, which is absent from the otherwise similar secretory form[1,2]. Alternative explanations have also considered the possibility that differences in glycosylation of the receptor form could cause conformational changes which would favour membrane binding[2].

There has been a steady accumulation of indirect evidence as to the manner of membrane binding by receptor immunoglobulin. The μ chain from radioiodinated splenocyte receptor IgM has been shown to be of higher molecular weight than its secreted counterpart by SDS-polyacrylamide gel electrophoresis (SDS-PAGE)[3]. We have made a similar observation for receptor IgM and IgG μ and γ chains synthesized in several human lymphoid cell lines[4], and a similar phenomenon has been reported for receptor IgM of a mouse lymphoid cell line[5]. Buoyant density and solubility measurements in the presence of non-ionic detergents have shown a greater hydrophobicity for receptor IgM, as opposed to secretory IgM[6,7]. In spite of these findings, the basis for the observed differences in receptor and secretory immunoglobulins remained unclear. The apparent molecular weight differences could be due either to variation in the

extent of glycosylation or to a difference in polypeptide chain lengths. More recently, carboxypeptidase digestion and peptide mapping techniques have been used in several laboratories[5,8,9] to analyse membrane associated μ chains for a modified C-terminus. These studies have so far yielded conflicting results, which, in some experiments, may be due to contamination by the secretory μ-chain species.

A separate but related question to the structure of receptor immunoglobulin concerns the biosynthetic pathway which distinguishes it from secretory immunoglobulin. Previous models[10,11] have proposed that divergence of the pathways occurs just before secretion, based on the finding that intracellular transport of both forms is very similar[12,13]. However, investigations of the events preceding synthesis of the polypeptide chains have not been previously reported.

In this article we report on the structure and biosynthesis of receptor IgM chains in human lymphoid cells representing various stages of B-lymphocyte differentiation and immunoglobulin expression. We have used the drug tunicamycin as an inhibitor of glycosylation. Size comparisons of non-glycosylated μ chains indicate that the membrane form has a larger polypeptide chain than the secretory form. The larger membrane form of μ chain was isolated and shown by carboxypeptidase digestion to have a modified C-terminus (but a normal N-terminal sequence) relative to secretory μ chain, consistent with the presence on receptor μ chain of a C-terminal peptide, possibly hydrophobic in nature, capable of interaction with the plasma membrane. Unexpectedly, two forms of μ chain were detected intracellularly in Daudi and Raji nonsecretory cells, one resembling the membrane form and one resembling the secretory form with the former predominating in Daudi cells and the latter form predominating in Raji cells. This same pattern of μ-chain expression was found by cell-free translation of Daudi and Raji mRNA, indicating that the two forms of μ chain can be

---

*Present address: Max-Planck-Institut für Biologie, Corrensstrasse 42, 7400 Tübingen 1, FRG.

produced in the same cell by simultaneous translation of different mRNA molecules.

Cell lines with qualitatively and quantitatively different immunoglobulin biosynthetic capacities were chosen for examination (Table 1). Raji and Daudi cells each devote about 0.5% of their total protein synthesis to immunoglobulin production. Daudi cells deposit most of this immunoglobulin on the plasma membrane. Raji cells, by contrast, deposit very little of the immunoglobulin on the surface in a form detectable either by fluorescent antibody probes or by surface radioiodination. This comparison suggests that Raji more closely resembles a pre-B lymphocyte, while Daudi appears to be an analogue of a more mature B lymphocyte. RPMI 1788 is a high-rate IgM secreting lymphoblastoid cell line.

Our findings on the intracellular synthesis of membrane and secretory type μ chains reveal several unexpected features in the intracellular processing of μ chains by Daudi and Raji cells (Table 1). These features are discussed further below, and include the expression in characteristic ratios of two forms of μ chain by cell-free translation of isolated mRNA and in tunicamycin-treated cells, apparent lag in processing of leader sequences as revealed in the presence of tunicamycin, and probable unequal glycosylation of the two μ-chain forms.
Analysis of the amino- and carboxy-terminal sequences of surface μ chains

The intracellular forms of μ chain found in nonsecretory and secretory cells can be distinguished from each other and isolated by immunoprecipitation and SDS-PAGE. Analytical characterization of the intracellular μ chains of Daudi, Raji and RPMI 1788 is shown in Fig. 1. The intracellular form of μ chain radiolabelled during a 1-h exposure of Daudi (lane 4) or Raji (lane 5) cells to ^{35}S-labelled methionine is of similar apparent molecular weight and is distinct from the lower molecular weight intracellular μ chain of the high rate secreting cell RPMI 1788 (lane 6).

The higher molecular weight of the surface μ chain could be due to either extra carbohydrate or an extra peptide at either amino-terminal or carboxy-terminal ends of the secreted μ chain. The hypothesis that surface μ chain contains an extra peptide was tested by analysis of the amino- and carboxy-terminal amino acid sequences of biosynthetically labelled μ chains. The partial amino-terminal sequences of Daudi and Raji μ chains (Fig. 2) show that each has a pattern of valine and leucine residues corresponding to the prototype $V_H III$) subgroup sequence. The period of labelling with radioactive valine and leucine was shorter than the turnover time for membrane immunoglobulin. Consequently these sequences establish that neither Raji nor Daudi μ chains retain the hydrophobic amino-terminal precursor peptide sequence, with which H chain synthesis is initiated, long enough for it to serve as a surface membrane insertion site. The μ chain of RPMI 1788 was subjected to similar analysis but proved to have a blocked amino terminus. In the absence of other sequence information, this blocked amino terminus is consistent with processing of the precursor peptide as expected for a secretory μ chain.

For comparative carboxy-terminal analysis of surface and secreted μ chains the enzyme carboxypeptidase-A was used. The carboxy-terminal residue to secretory μ chain is tyrosine[14], and carboxypeptidase-A will rapidly and completely remove a C-terminal tyrosine residue[15]. If surface μ chains possess an extra carboxy-terminal peptide they would not be expected to have a terminal tyrosine residue. This,

(+) with tunicamycin

Fig. 1 SDS-PAGE of biosynthetically labelled μ chains from tunicamycin treated and untreated cells. Log phase cultures were incubated with tunicamycin (0.5 μg ml⁻¹) for 4 h. Parallel untreated cultures were also maintained. 1×10^6 cells were collected for a 1-h pulse labelling in 0.2 ml medium containing no exogenous methionine and supplemented with 100 μCi ^{35}S-methionine (500 Ci mmol⁻¹). Complete RPMI 1640 medium (0.8 ml) supplemented with 15% fetal calf serum (growth medium) was added and incubation continued for 2 h. For the treated cultures, tunicamycin (0.5 μg ml⁻¹) was present throughout the labelling and chase periods. Cells were separated from culture medium and lysed by the addition of 0.2 ml ice cold lysis buffer (0.15 M NaCl, 1% Nonidet P-40, 1 mM phenylmethylsulphonylfluoride, pepstatin A (0.7 μg ml⁻¹), 25 mM Tris-HCl pH 8.2). Cell lysates were successively centrifuged to remove nuclei (1,000g, 10 min) and cellular debris (30,000g, 30 min) and labelled IgM was immunoprecipitated by addition of 10 μg affinity purified rabbit anti-human IgM antibody (15 min at 20°) and 25 μl of 10% solution of formalin-fixed, protein A-bearing *Staphylococcus aureus* organisms (Cowan 1 strain)[35]. The immunoprecipitates were washed three times with 0.5-ml aliquots of lysis buffer, heated to 100 °C for 2 min in SDS-PAGE sample buffer (2% SDS, 0.1 M dithiothreitol, 10% glycerol, 0.01 mg ml⁻¹ bromphenol blue dye, 0.065 M Tris-HCl pH 6.8), and electrophoresed in a 10% polyacrylamide slab gel according to the method of Laemmli[36]. Radioactive components were visualized by fluorography[37] (exposures of 2–24 h). The positions of glycosylated and non-glycosylated μ chains are indicated in the margin. Lanes 1, 2, 3, 8 and 9, tunicamycin treated; lanes 4, 5, 6 and 7, untreated cells.

V$_H$III   EVQLVESGGGLVQPGGSLRL

Fig. 2 Partial amino-terminal amino acid sequences of μ chains. The μ chains of Raji and Daudi cell IgM were biosynthetically labelled with ³H-leucine (55 Ci mmol⁻¹) and ³H-valine (36 Ci mmol⁻¹) and isolated by immune precipitation and SDS-PAGE as described in legends to Figs 1 and 3. Amino acid sequences were determined by automated Edman degradation performed on a Beckman 890C sequenator. Repetitive yield at each cycle determined by internal standards was 88–92%. Separate sequencer runs were performed for each sample labelled with each amino acid. The V$_H$III prototype sequence is from ref. 38.

approach has already been used to investigate the carboxy terminus of μ chains from the human cell line Bri-8 and the mouse myeloma tumour McPc 1748 (ref. 8), as well as the mouse B cell line 38C-13 (ref. 5). In all three cases there was significant release of radioactive tyrosine from μ chain by carboxypeptidase-A treatment. However, in those studies there was no convincing demonstration that the μ chains investigated were of the surface form. Also there was a lack of kinetic evidence to support the proposal that the tyrosine residues released were indeed carboxy-terminal. The Bri-8 cell line studied in this laboratory is a high-rate IgM secreting line. Recently carboxypeptidase-A digestion of Daudi μ chain has been reported to release fractional molar amounts of several amino acids, including tyrosine, but kinetics suggested that valine is located closer to the carboxy terminus than tyrosine[9]. For the present studies Daudi, Raji, RPMI 1788 and Bri-8 cells were labelled for 1 h with ³H-tyrosine and the intracellular μ chains and L chains isolated by immunoprecipitation and SDS-PAGE. Patterns similar to those shown in Fig. 1 (lanes 4–6) were obtained and individual μ chains and light chains were eluted from the appropriate regions of the gel. The kinetics of carboxypeptidase-A catalysed release of ³H-tyrosine from these isolated chains is shown in Fig. 3. For the μ chains of secreted IgM of RPMI 1788 and Bri-8 approximately 1 mol of tyrosine is released per chain during 2 min of incubation. This finding is consistent with the kinetics of release of carboxy terminal tyrosine from aldolase[16]. Carboxypeptidase analysis of the ³H-tyrosine labelled light chains of RPMI 1788, Bri-8 and Raji shows no release of tyrosine. This is consistent with known sequences and established the low background in this analysis. The intracellular μ chains of characteristic surface size isolated from Daudi and Raji cells showed a partial release of tyrosine in the carboxypeptidase-A analysis (Fig. 3). Tyrosine was released from Daudi and Raji μ chains with kinetics indicating a carboxy-terminal location, but with the yield in both cases significantly lower than expected. The yields of tyrosine released correspond to approximately 0.35 mol for Daudi and 0.7 mol for Raji μ chain (based on an estimate of 20 tyrosine residues per chain). The simplest interpretation of these results is that Daudi and Raji cells contain, in different proportions, two different forms of μ chain, only one of which has a carboxy-terminal tyrosine residue.

Analysis of non-glycosylated μ chains

Human μ chains are glycosylated at five asparagine residues and the carboxydrate side chains constitute approximately 15% of the molecular weight of human IgM[17–19]. To test the hypothesis that the difference in molecular weight between

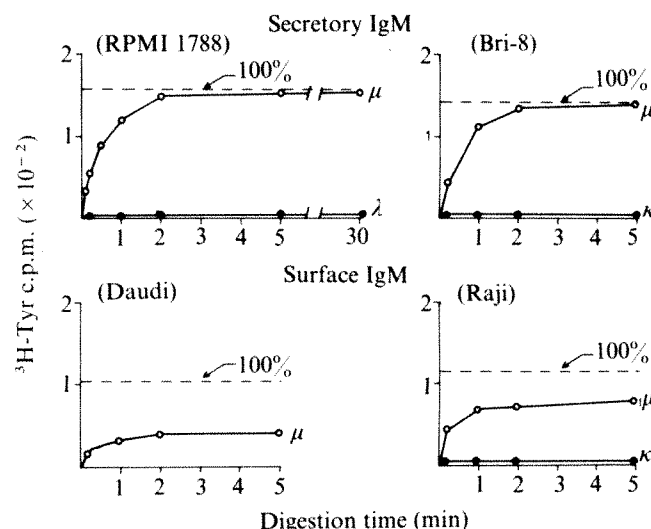
surface and secreted μ chains could be due to a difference in the extent of glycosylation, the drug tunicamycin was used to inhibit glycosylation during μ chain biosynthesis. Tunicamycin has been shown to act by inhibiting the formation of N-acetylglucosamine lipid intermediates[20], which serve as donors for the synthesis of the core regions of asparagine-linked oligosaccharides[21]. Biosynthesis of completely non-glycosylated μ chains was effected by preincubating the lymphoid cells with tunicamycin in limiting conditions[22]. SDS-PAGE analyses of the non-glycosylated μ chains are shown in Fig. 1 and in more detail in Fig. 4. The intracellular form of secretory μ chain from tunicamycin treated RPMI 1788 cells is a single band (lane 9, Fig. 4) with a considerably lower apparent molecular weight than the glycosylated intracellular μ chain of RPMI 1788 (lane 3) or the glycosylated


Fig. 3 Carboxy-terminal tyrosine released from intracellular μ chains of the pre-membrane and pre-secretory types. Log phase cells (5 × 10⁶ per ml) were labelled for 1 h in either 0.2 ml (Bri-8, RPMI 1788) for 0.5 ml (Daudi, Raji) RPMI 1640 lacking exogenous tyrosine and supplemented with ³H-tyrosine (500 μCi ml⁻¹; 40 Ci mmol⁻¹). Cell lysis, anti-μ immunoprecipitations, SDS-PAGE and fluorography were done as described for Fig. 1. The fluorography of the gel (not shown) revealed μ and light chain bands similar to those shown in Fig. 1, lanes 4, 5 and 6 (Bri-8 μ-chain mobility was indistinguishable from that of RPMI 1788). Bands were located by overlaying the dried gel with the fluorographic negative. Gel pieces containing the bands were sliced out and the material eluted overnight at 60 °C in 0.5 ml elution buffer (2% SDS, 20 mM dithiothreitol, 0.25 M Tris-HCl, pH 8.2). After removal of the gel slices, 0.5 mg bovine serum albumin (as carrier) and freshly recrystallized iodoacetamide (final concentration 50 mM) were added and the samples incubated in the dark at 20 °C for 30 min. The proteins were precipitated with acetone (five volumes), collected by centrifugation, and washed twice with acetone:water (5:1 v/v). The air-dried precipitates were dissolved by heating at 100 °C for 2 min in 0.9 ml digestion buffer (0.2 M LiCl, 50 mM NaHCO₃). Insoluble material (less than 10% of the radioactivity) was removed by centrifugation, and the samples adjusted to pH 8.0 with 0.5 M NaOH. Crystals of carboxypeptidase A (Worthington Biochemicals) were washed with water and dissolved in 10% LiCl at 0.2 mg ml⁻¹ ($A_{280}/2.3$ = mg ml⁻¹). Digestions (enzyme:substrate = 1:100) were initiated by addition at 20 °C of 10 μl enzyme solution with rapid mixing. Aliquots (150 μl) of reaction mixture were removed at the times indicated, immediately added to 50 μl ice cold 40% trichloroacetic acid, for determination of released ³H-tyrosine (acid-soluble) fraction. The hypothetical 100% release values are based on an estimated 20 tyrosine residues per μ chain (or 18 for RPMI 1788).

Table 1 Summary of μ-chain expression in the cell lines investigated

	IgM expression*		μ Chains detected intracellularly‡			μ chains detected by cell-free translation
	Membrane	Secretory	Level†	Glycosylated	Non-glycosylated	
Daudi	+ + +	−	0.5%	MEMBRANE / secretory } §	PREMEMBRANE presecretory	PREMEMBRANE presecretory
Raji	+	−	0.5%	membrane / SECRETORY } §	premembrane PRESECRETORY	premembrane PRESECRETORY
RPMI 1788	±	+ + +	5–10%	SECRETORY	PROCESSED SECRETORY	PRESECRETORY

CAPITALS designate the predominant or only form detected.

*Qualitative expression as determined by using fluorescent antibody, surface radioiodination and biosynthesis techniques.

†Incorporation of ^{35}S-methionine into anti-μ precipitable relative to trichloroacetic acid precipitable cellular proteins during a 60-min labelling.

‡Species labelled with ^{35}S-methionine during a 15–60-min pulse, resolved by SDS-PAGE and/or characterized by C-terminal analysis. Terminology as follows: membrane—membrane μ chain lacking C-terminal tyrosine; secretory—secretory μ chain with C-terminal tyrosine; presecretory and premembrane—respectively μ-chain forms with presumed N-terminal leader sequence; processed secretory—indicates cleavage of N-terminal leader sequence. The presence or absence of the N-terminal leader sequence (that is, yielding pre or processed μ chain respectively) can be assessed by comparison of the mobilities on SDS-PAGE of non-glycosylated μ chains with the products of cell-free translation of μ-chain mRNA.

§These are detected by SDS-PAGE as one band of membrane μ-chain size, however C-terminal analysis of glycosylated chains is consistent with the indicated composition. The processing of glycosylated chains cannot be resolved by SDS-PAGE analysis but amino-terminal sequence analysis (Fig. 2) shows that processing is complete within 6 h after synthesis.

extracellular μ chain (lane 7, Fig. 1). The non-glycosylated μ chains of Raji and Daudi intracellular IgM are resolved into two forms (lanes 7, 8, Fig. 4) differing from one another in their apparent molecular weights. The lower molecular weight μ chains of Daudi and Raji are similar in mobility to each other and have a perceptibly lower mobility than the non-glycosylated μ chain of RPMI 1788 cells (lane 9). The major difference between Daudi and Raji profiles is in the intensity of the labelling of the two forms of μ chain, with the higher molecular weight form of μ chain predominating in Daudi, and the lower molecular weight form predominating in Raji. The existence of two forms of μ chains in Daudi and Raji cells confirms the prediction made on the basis of the carboxy-terminal analysis as discussed above. Comparison of the relative proportions of the two forms of μ chain with the differential release of tyrosine from Daudi and Raji μ chains is consistent with the interpretation that the higher molecular weight form of both Daudi and Raji μ chain lacks carboxy-terminal tyrosine and the lower molecular weight form has a carboxy-terminal tyrosine residue (thus being analogous to the secreted μ chain of similar apparent molecular weight). On this hypothesis the higher molecular weight form of μ chain in Raji and Daudi cells is the precursor of surface μ chain, and the molecular weight difference relative to the secretory μ chain is due to an extra carboxy-terminal peptide attached to the secretory μ-chain sequence and preventing carboxypeptidase catalysed release of the carboxy-terminal tyrosine. Evidence consistent with this hypothesis was obtained by separation of the two forms of non-glycosylated Daudi μ chain biosynthetically labelled with tyrosine and subsequent carboxypeptidase digestion. The higher molecular weight form of μ chain has essentially no carboxypeptidase-releasable tyrosine while the lower molecular weight form of μ chain yields a mole of tyrosine and kinetics consistent with tyrosine being the carboxy-terminal residue (Fig. 5). A similar analysis of the two Raji μ chains (not shown) yielded similar results.
